convective clouds. In reality, however, some cold fronts do not have coincident wind and temperature changes (e.g., Schultz, 2004, 2005), are not coincident with clouds and precipitation (e.g., Mass and Schultz, 1993), or may not even be associated with temperature drops because cold air pooled in valleys ahead of the front may be colder than the postcold frontal air (e.g., Sanders and Kessler, 1999; Doswell and Haugland, 2007). Thus, the representation of cold fronts should be modified to encompass these cold fronts that do not meet the traditional criteria.

Different types of cold fronts exist, classified by their direction of motion (e.g., backdoor cold fronts), location (e.g., southerly buster), or a combination of both (e.g., arctic fronts). For example, a backdoor cold front is one that moves westward (against the prevailing westerlies). In the United States, a New England backdoor cold front is associated with the westward expansion of a cold surface high-pressure system situated near the North Atlantic coast during winter (Bosart et al., 1973; Hakim, 1992). The thermal gradient is reversed in this case, and the frontal zone is characterized by fog and low stratiform clouds formed from evaporation of moisture from the ocean. This cold front moves southward along the eastern slope of the Appalachian Mountains, which serve as a barrier to inland penetration.

The southerly buster or southerly burster is an intense summertime cold front that arrives at the southeastern tip of Australia from the Southern Ocean (Baines, 1980). Arrival of this front in the afternoon can be accompanied by temperature changes of 10–15°C over a period of a few minutes, but precipitation is not usually associated with a southerly buster. The front travels equatorward, acquiring a characteristic S-shape as its movement is inhibited by the east coast mountain chain, but movement inland and along coastal waters is less restrained.

Another subclass of cold fronts associated with the advection of arctic air equatorward is an arctic front (e.g., Wang et al., 1995). Dramatic examples of these kinds of fronts occur in the central United States, with the cold air traveling as far equatorward as Central America (e.g., Schultz et al., 1997, 1998). The bitter cold air behind the front is formed from strong radiational cooling in the arctic region (Emanuel, 2008).

Warm Fronts

Warm fronts are characterized by the advection of warm air into cold air. The leading edge of the warm front is delineated by the semicircles that point in the direction of movement of the warm air (Figure 1). Traditionally, a vertical cross section through a warm front shows a gently sloping zone over the cold air. Above the strongly sheared zone, warm air gently rises over the warm front. At the surface, a warm frontal passage would be characterized by increasing temperature and dew point, and a cyclonic wind shift. A sequence of clouds would progress from cirrus to altocumulus to nimbostratus before the frontal passage, followed by clearing skies after frontal passage.

A more modern characterization of warm fronts indicates that the flow over the warm front may not be characterized by gentle ascent. Instead, the flow may consist of convective elements embedded within the ascent (the so-called escalator–elevator paradigm of Neiman et al., 1993) or may be

characterized by banded convective precipitation (e.g., Novak et al., 2004).

Stationary Fronts

As the name implies, a stationary front has historically been classified as a front that is not moving or moving very slowly. The stationary front is denoted on the surface map by alternating triangles that point away from the cold air side of the front and semicircles that point away from the warm air side of the front, indicating the standoff between the advance of the cold air and the advance of the warm air. This type of front may reflect either a change in the synoptic-scale circulation pattern that halts the translation of the frontal zone or the heterogeneity of the Earth's surface that provides conditions to fix a frontal transition zone to a preferred location.

Schematics of stationary fronts are similar to warm fronts with their gentle slope. Stationary fronts have since been recognized to have either the slope of warm fronts or cold fronts. In fact, some stationary fronts in the central United States transition rapidly from moving equatorward as cold fronts, to becoming stationary, to moving poleward as warm fronts (Bosart et al., 2008). Consequently, a modern interpretation of a stationary front would be to continue to analyze fronts as stationary fronts, but not to apply any given conceptual model to it.

Another example of a stationary front is a coastal front. Coastal fronts are frontal zones separating relatively warm oceanic air from colder continental air, such as along the East Coast of the United States in winter. Such environments promote the formation of a stationary front (Bosart et al., 1972; Bosart, 1975). Although these fronts exhibit transition zones that are comparable to those of a cold front, they are of limited extent, ranging from 200 to 600 km, and of limited duration, lasting up to a day or less. Coastal fronts often result in bands of precipitation, parallel to the front, with the maximum precipitation occurring on the cold side, and possibly a transition from snow to sleet to freezing rain to rain on the warm side.

Occluded Fronts

Traditionally, occluded fronts were considered to be the end products of the evolution of extratropical cyclones, formed by the catch-up of a slower-moving warm front by a faster-moving cold front. The occluded front is denoted on the surface map by alternating triangles and semicircles that point in the direction of movement (Figure 1). Two kinds of occluded fronts were hypothesized to exist: warm-type occlusions and cold-type occlusions. Warm-type occlusions were hypothesized to form if the air ahead of the warm front was colder than the air behind the cold front, lifting the merging cold front over the warm front. In contrast, cold-type occlusions were hypothesized to form if the air ahead of the warm front was warmer than the air behind the cold front, lifting the merging warm front over the cold front.

This traditional explanation does not adequately explain the structure and evolution of occluded fronts. First, much of the length of some occluded fronts is formed, not by the catch up of fronts, but by the lengthening of the front by deformation

due to differential rotation around the cyclone. Second, many cyclones continue to deepen after the formation of the occluded front. In fact, the heaviest precipitation and the strongest winds in the cyclone typically occur after the occluded front has formed. Third, few well-documented examples of cold-type occlusions exist; yet this is not explained by the traditional model.

To address these inadequacies, Schultz and Vaughan (2011) presented a more modern interpretation that ascribes occluded fronts to the wrap up of the cold and warm fronts around an extratropical cyclone. The extreme length of some occluded fronts is better characterized as the wrap up of the warm sector and occluded front than by the catch up of one front by another. In the wrap-up paradigm, the formation of an occluded front no longer determines the end of deepening of the cyclone, but is a result of the deepening. The deeper the cyclone, the more likely a cyclone will form an occluded front. The wrap-up paradigm also explains why many weak cyclones do not form occluded fronts.

Also in the wrap-up paradigm, the two kinds of occluded fronts are not determined by the relative temperatures across the occluded front, but by their relative static stabilities (Stoeckling et al., 2002). Warm-type occlusions form if the warm frontal zone is more stable than the cold frontal zone, and cold-type occlusions form if the cold frontal zone is more stable than the warm frontal zone. Because warm frontal zones tend to be much more stable than warm frontal zones, warm-type occluded fronts would be more common, explaining the relative dearth of cold-type occlusions.

Closely related to an occluded front is a back-bent front (e.g., Bjerknes, 1930; Bergeron, 1937; Shapiro and Keyser, 1990). This front is a warm or occluded front that has been wrapped around the cyclone, enclosing a region of relatively warm postcold frontal air. A region of strong winds known as the sting jet is sometimes found along a back-bent front (Grønås, 1995; Browning, 2004; Schultz and Sienkiewicz, 2013).

Dryline

The dryline is a zone of strong dew-point temperature gradient that forms in the southern United States during the warm season, separating moist air originating from the Gulf of Mexico from drier air originating from the southwest United States (Schaefer, 1974, 1986; Hoch and Markowski, 2005). Although not a front per se, the dryline is a boundary between two synoptic-scale air masses and can sometimes possess frontal characteristics of a temperature gradient and wind shift (Ziegler and Hane, 1993; Buban et al., 2007). Like fronts, the strength of the dryline (magnitude of the gradient of the dew point temperature) can be regulated by deformation and convergence (Schultz et al., 2007). Temperature differences across the dryline can be enhanced by the differing moisture contents in the air (i.e., moist air cools down more slowly than dry air because of the greenhouse effect of the water vapor).

Upper-Level Fronts

An upper-level front is a transition zone exhibiting a sharp thermal contrast and wind shear that may extend from the tropopause down to as low as 2–3 km above the ground. The mature upper-level frontal structure displayed in Figure 2 shows a frontal zone depicted by the concentration of isentropes (lines of constant potential temperature). Upper-level fronts are approximately 50–200 km wide and hundreds of kilometers long. These fronts are not described as cold or warm fronts, although cold-air and warm-air advections often occur along its length (Keyser and Shapiro, 1986; Schultz and Doswell, 1999). Upper-level fronts are not usually associated with the type of weather that characterizes surface fronts. Clear-air turbulence and stratospheric–tropospheric exchange of air are often defining characteristics that distinguish upper-level fronts.

Figure 2 Cross section of an upper-level front. The tropopause is denoted by thick solid lines. The thin dashed lines are isentropes (K), and the thin solid lines are isotachs (m s^{-1}). J denotes the axis of the jet stream, directed out of the section. Pressure levels (hPa) and standard heights (km) are shown on the abscissa. Adapted with permission from Reed, R.J., 1955. A study of a characteristic type of upper-level frontogenesis. *Journal of Meteorology* 12, 226–237.

Figure 3 Schematic illustration of the transverse secondary circulation associated with an upper-level front as shown in [Figure 2](#). Adapted with permission from Danielson, E.F., 1968. Stratospheric–tropospheric exchange based on radioactivity, ozone and potential vorticity. *Journal of the Atmospheric Sciences* 25, 502–518.

Superposed on this front and jet-stream system is a transverse or cross-front circulation ([Eliassen, 1990](#); [Figure 3](#)). This circulation provides a consistent explanation of how the upper-level front is maintained and why stratospheric constituents, such as ozone and high-level radioactivity from nuclear explosions, can be observed in the lower troposphere. The subsiding branch maintains the most prominent characteristics of the upper-level front. In particular, the descent of stratospheric air within a narrow pocket can deform the tropopause into what is called a tropopause fold.

Thermal wind balance provides the explanation for the high-speed jet flow above the frontal zone. In this example, the sharp thermal gradient across the front produces a relatively strong jet that flows southward. Two characteristic features of an upper-level front are cyclonic shear and the temperature gradient. These two features are always associated with the development and enhancement of a prominent upper-level jet and frontal system, and with surface-based fronts that extend to the upper troposphere.

Surface Fronts Associated with Mesoscale Phenomena

Extratropical cyclones are not the only weather systems that organize temperature gradients and wind shifts into fronts; mesoscale phenomena can also do so. Small-scale fronts occupy a relatively limited horizontal domain, have relatively short lifetimes, and are surface-based phenomena. Because they exist only for a few minutes to a few hours, the Coriolis force is usually not dominant, but the nonhydrostatic acceleration may be important in the dynamics of these fronts.

Consequently, these fronts may take the form of a density current. In this section, three types of fronts associated with mesoscale phenomena are discussed: sea-breeze fronts, gust fronts associated with convective storms, and drainage fronts.

Sea-Breeze Fronts

Coastlines are prime regions for strong temperature differences to develop and take the form of fronts. Like the dryline, temperature gradients across the coast may develop in a diurnal cycle. Air masses over the water tend to heat up less during the day and cool down less during the night than adjacent air masses over the land. A pressure gradient, which develops in response to this differential heating, drives an onshore flow at low levels, with a return flow at about 1–2 km above the surface. The leading edge of the cooler air may develop frontal characteristics. The sea-breeze front is characterized by both a sharp temperature drop of several degrees centigrade or more and a marked increase in the humidity that can occur over a horizontal distance of a kilometer or less. Sea-breeze fronts are most prominent in the warm part of the year under relatively benign synoptic-scale flow. Inland penetration of the sea-breeze front by 10 km or more may be opposed by an offshore wind ahead of the front and by turbulent convective mixing over land, which tends to weaken the temperature and humidity gradient across the frontal zone.

Gust Fronts

Convective storms are associated with the ascent of warm, moist, unstable air. To maintain conservation of mass, descent must accompany the storms. The cooler descending air reaches

the surface and spreads out. The leading edge of this air is called a gust front and can frequently possess the characteristics of a front. The gust front develops from evaporative cooling associated with precipitation below large convective clouds. Its vertical extent is limited by the height of the cloud base, usually below 2 km. Temperature changes as high as 10° C over a few tens of meters can occur, and the wind gusts may represent a danger to aircraft that attempt to land on runways where gust fronts are evident. A gust front will last only minutes or tens of minutes if the cold air moves away from its source. It may, however, persist for a few hours or more if the cold air below the cloud base moves with the convective system. Relatively warm, moist air ahead of the front moves up and along the frontal surface to the cloud base in order to maintain the convection and precipitation that ultimately drives the gust front.

Drainage Front

A drainage front is the leading edge of downslope drainage of cold air from high elevations. Drainage currents develop at night, and the most favorable conditions for occurrence are usually met during the fall under clear skies and light winds. A pressure differential develops between the air over the slope and air at the same level over the level terrain. This pressure gradient force, together with gravity, drives a downslope cold current of air with a temperature differential at its leading edge. The distinguishing characteristics of the topography and the depth of radiatively cooled air along the slope will determine the frontal characteristics. Compressional heating during descent will also modify the cold temperatures behind the front, but temperature drops of 5° C are not uncommon after frontal passage. Humidity changes are usually not considered a significant factor in this type of front, but relatively light and gusty winds of about 5 m s⁻¹ are often encountered.

Fronts in the Lower Stratosphere

AL Lang, University of Albany – State University of New York, Albany, NY, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

A jet streak located along the sloping midlatitude tropopause has mesoscale structure in both the upper troposphere and lower stratosphere. This article explores the historical to modern day observation, theory, and dynamical insight into the structure and evolution of the lower stratospheric portion of the tropopause jet, known as the lower stratospheric front.

Introduction

Tropopause jet-front systems are transient yet pervasive dynamic and thermodynamic features are found in the vicinity of the sloping midlatitude tropopause. These systems, also known as upper-level jet-front systems, are characterized by a local wind speed maximum (i.e., the jet core) along the tropopause surface. Through the thermal wind relationship, the regions of vertical shear located above and below the jet core are directly associated with attendant baroclinic zones (i.e., the fronts). A characteristic example of the structure of a tropopause jet-front system is represented by the vertical cross section taken across the direction of the flow depicted in [Figure 1](#). As deep, three-dimensional, features centered about the tropopause, tropopause jet-front systems have significant vorticity and thermal structures residing both in the upper troposphere (upper tropospheric front, labeled 'UT Front' in [Figure 1](#)) and in the lower stratosphere (lower stratospheric front, labeled 'LS Front' in [Figure 1](#)). The majority of research attention regarding tropopause jet-front systems has been focused on the upper tropospheric portions of these systems, while a disproportionally small fraction of research attention has been given to the portions of these structures that reside above the jet core, within the lower stratosphere. Since the mid-twentieth century, the structure, evolution, and life cycle of these tropopause jet-front systems have been studied in a variety of contexts, including clear air turbulence, stratosphere–troposphere exchange, and chemical transport, as well as the extratropical cyclone life cycle.

This article will provide a historical perspective on, as well as our current understanding of, lower stratospheric portion of tropopause jet-front systems. This article is structured in the following manner. In order to fully explore the relevance of the lower stratospheric portion of tropopause jet-front systems, a background in the upper tropospheric portion of these systems is provided in [Section Background](#). A historical perspective of research on the lower stratospheric portion of the midlatitude jet is provided in [Section Historical Perspective](#). An examination of the typical structure and evolution of a lower stratospheric front within a baroclinic wave is presented in [Section Structure and Evolution](#). [Section The Role of Tropospheric Latent Heating in Lower Stratospheric Frontogenesis](#) provides details on the role of tropospheric latent heating on lower stratospheric fronts. Finally, [Section The Role of the Midlatitude Lower Stratospheric Structure in Large-Scale Circulations](#) explores a large-scale view of the role of the

lower stratospheric front by considering them as they are represented in a zonally averaged perspective.

Background

Much of what is currently known about the role of the tropopause jet-front system in weather and climate has centered on the life cycle and associated implications of the upper tropospheric component of these systems, known as upper-level fronts or upper tropospheric fronts. The process of upper tropospheric frontogenesis has been shown to be an important process in the development and life cycle of surface cyclones. The ageostrophic transverse vertical circulation associated with a dynamically active tropopause jet-front system not only provides the cross-stream differential subsidence required to intensify the upper tropospheric front, but also simultaneously steepens and lowers the dynamic tropopause below the jet core. This process forces a thin wedge of stratospheric air, characterized by large (small) values of potential vorticity (PV, water vapor), downward into the upper and middle troposphere. Within the upper troposphere, the large values of PV are manifested as a local maximum in absolute vorticity. The local maximum in absolute vorticity within the developing upper tropospheric front can subsequently provide a precursor disturbance to a wave scale surface cyclogenesis event. Thus, the development of an upper tropospheric vorticity maximum in the upper tropospheric frontogenesis process implicates the tropopause jet-front systems in the incipient stages of the extratropical cyclone life cycle.

Additionally, the folding of the dynamic tropopause in association with intense upper tropospheric frontogenesis is one of the most efficient and dominant forms of stratosphere–troposphere exchange in the midlatitudes. In the 1960s, the US Defense Atomic Support Agency and the Atomic Energy Commission supported a field campaign to document the pathway of radioactive fallout from the stratospheric atomic weapons testing. The campaign, known as Project Springfield, confirmed the theoretical role of individual tropopause jet-front systems, specifically the upper tropospheric front, in stratosphere–troposphere exchange. The substantial displacements of the dynamic tropopause on isentropic surfaces that occur within tropopause folds facilitate the exchange of mass across the tropopause. As a result of the synoptic and mesoscale processes in the vicinity of a tropopause fold, dry, ozone-rich stratospheric air descends into the troposphere and can

Figure 1 Cross section the North Atlantic jet off the east coast of North America at 1200 UTC 27 February 2008, highlighting the jet core (marked with a 'J') and associated frontal structures. The upper tropospheric front is labeled 'UTF' and the lower stratospheric front is labeled 'LSF.' Isotachs are thick lines every 10 m s^{-1} beginning at 40 m s^{-1} , isentropes are thin lines every 4 K , and the magnitude of the horizontal potential temperature gradient is filled every $1 \text{ K (100 km)}^{-1}$ beginning at $2 \text{ K (100 km)}^{-1}$. irreversibly mix with tropospheric air. It is hypothesized that at least 10% of global tropospheric ozone originates from the stratosphere via intense upper tropospheric frontogenesis and tropopause folding.

Historical Perspective

Observation

In one of the first conceptual models of a jet-front system, Swedish meteorologist Roy Berggren proposed that a continuous frontal zone (at the time, known as the polar front)

stretched upward from the surface, through the upper troposphere and into the lower stratosphere (Figure 2). The controversial model applied the concept of a 'front' to upper air observations from the high spatial and temporal resolution European sounding network. The conceptual model suggested that in the upper troposphere, the 'front' was characterized by mesoscale gradients of temperature as well as cyclonic shear. At the level of maximum wind the 'front' was manifested solely as a mesoscale zone of cyclonic shear, while in the lower stratosphere, where the gradient of temperature reversed above the jet core, the 'front' once again was characterized by both temperature gradients and cyclonic shear. This proposed

The shaded area represents a continuous frontal zone as described by Berggren (1952). Adapted from Berggren, R., 1952. The distribution of temperature and wind connected with active tropical air in the higher troposphere and some remarks concerning clear air turbulence at high altitude. *Tellus* 4, 43–53 under the terms of the Creative Commons Attribution-Noncommercial 3.0 Unported License (<http://creativecommons.org/licenses/by-nc/3.0/>).

model, which included mesoscale structures at and above the jet core, was largely dismissed as lack of consistent balloon observation of the lower stratosphere. Berggren's conceptual model subsequently led researchers to question the scale of the vorticity and baroclinic structures in the lower stratosphere. Utilizing the (lower resolution) US sounding network, researchers argued that the lower stratospheric structure was not confined to the mesoscale, but rather was on the larger synoptic scale and thus did not fit the 'frontal' model. Subsequent research attention remain focused on the more consistently and conveniently observable upper tropospheric half of these systems. The focus on the upper tropospheric portion of the tropopause jet-front system led to a fruitful avenue of research explaining linkages of the jet with surface cyclogenesis, stratosphere–troposphere exchange, and clear air turbulence.

It was not until the 1960s, when instrumented research aircraft observations in field campaigns became a routinely available supplement to conventional radiosonde data, that a much-improved resolution of tropopause jet-front system structures was afforded. By the 1970s, high-resolution aircraft measurements confirmed that there was indeed a mesoscale (~ 100 km) confinement of cyclonic wind shear below, at, and above the jet core. This observationally based analysis

supported the Berggren conceptual model of a mesoscale 'frontal' structure extending from the upper troposphere through the level of maximum wind, to the lower stratosphere.

Theory

Though the notion of one continuous mesoscale frontal structure extending through the tropopause was suggested by observational studies, the theoretical and idealized studies of tropopause jet-front systems support the notion that the jet core vertically separates two separate centers of frontogenetic forcing. This idea of two separate centers of frontogenetic forcing was supported by the fact that true fronts are regions characterized by both vertical and horizontal shears as well as locally enhanced static stability. Thus, the baroclinic zones in the upper troposphere and lower stratosphere can be characterized as two separate fronts, while the cyclonic shear region at the jet level characterized as frontal in the Berggren model lacks the characteristics of a true frontal zone.

Early analyses of lower stratospheric thermal structure in the midlatitudes revealed that above the jet core the warmest and coldest air were arranged in elongated parallel bands, horizontally separated by the local wind speed maximum. This configuration of the environment above the level of maximum

wind led several researchers in the 1940s to hypothesize that the wind and thermal fields above the jet were connected with a cross-stream vertical circulation. By virtue of the strong static stability of the lower stratosphere, the vertical motion in the vicinity of the jet was hypothesized to have a rather substantial effect on the horizontal thermal field via adiabatic warming and cooling. Investigations into the characteristics of the thermal structure above the jet core subsequently led to research inquiries aimed at describing the nature of the vertical circulations in the vicinity of the jet. By the late 1940s, a hypothesis was presented which suggested that superimposed on the wave scale vertical motion between a ridge and downstream trough were two separate, cross-stream vertical circulations associated with the midlatitude jet; one in the lower stratosphere above the jet core and another in the upper troposphere below the jet core (Figure 3). The upward and downward branches of these circulations, both in the upper troposphere and in the lower stratosphere, could independently act to enhance or weaken the wave-scale vertical motion associated with an upper-level trough. These early studies suggested that a combination of the jet circulations and the wave scale vertical motions would have a substantial effect on the production of sensible weather.

The pioneering work of the US synoptic meteorologists Richard Reed and Fred Sanders in the mid-1950s established that differential vertical motions near the jet were at the heart of upper tropospheric frontal development. In the vicinity of the tropopause, the differential tilting of isentropes associated with cross-stream gradients of vertical motion could create sloping stable layers, with roots in the lower stratosphere, that were characterized by large horizontal temperature gradients. The differential vertical motion would also act to tilt horizontally oriented vortex tubes (associated with the vertical shear) into a more vertical orientation, thus enhancing the vertical vorticity within the developing upper-level front.

In his extension of John S. Sawyer's study on jet circulation dynamics, Arnt Eliassen derived a mathematical formulation to calculate the important vertical circulation in the vicinity of the fronts. This equation, which has since become known as the Sawyer–Eliassen equation, was the first to make the mathematical connection between the primary forcing captured by geostrophic frontogenesis and the creation of a secondary

ageostrophic circulation in the vicinity of a frontal zone. Their equation,

$$2\gamma \left(-\frac{\partial u_g}{\partial x} \frac{\partial \theta}{\partial y} + \frac{\partial u_g}{\partial y} \frac{\partial \theta}{\partial x} \right) = -\gamma \frac{\partial \theta}{\partial x} \frac{\partial^2 \psi}{\partial y^2} + 2 \frac{\partial m}{\partial p} \frac{\partial^2 \psi}{\partial y \partial p} - \frac{\partial m}{\partial y} \frac{\partial^2 \psi}{\partial p^2}, \quad [1]$$

shows that in a coordinate system where the x -direction is oriented along a baroclinic zone, the geostrophic (subscript g) shearing and stretching deformation acting on a baroclinic zone (left-hand side) would force a secondary ageostrophic cross-stream circulation (stream function, ψ , in the right-hand side). In their equation, m is the geostrophic momentum ($u_g - fy$), $\gamma = \frac{R}{fP_0} \left(\frac{P_0}{P} \right)^{c_p/c_p}$ and is constant on a pressure (P) surface, $\frac{\partial \psi}{\partial y} = \omega$ and $-\frac{\partial \psi}{\partial p} = v_{ag}$. The application of the Sawyer–Eliassen equation suggested that frontogenesis was a two-step process in which (1) the deformation in the primary geostrophic flow provides forcing to tighten the temperature gradient, resulting in a secondary ageostrophic circulation, then (2) that secondary ageostrophic circulation potentially acts to further intensify the temperature gradient. The original analysis by Eliassen explored the idea that the geostrophic deformation in the vicinity of a tropopause jet-front system resulted in forcing for two separate secondary circulation cells, one above and one below the jet core. These two ageostrophic circulations were centered about the baroclinic zones lying above and below the level of maximum wind.

The secondary circulations associated with idealized variations of the geostrophic shearing and stretching deformation forcing in the vicinity of the tropospheric half of the tropopause jet-front system have also been considered in conceptual analyses. In the absence of temperature advection (e.g., a case of pure stretching deformation), the Sawyer–Eliassen circulations in the jet entrance and exit regions result in the traditional four-quadrant model; a thermally direct (indirect) circulation in the entrance (exit) region (Figure 4(a)). When geostrophic cold air advection was present through the jet core, the thermally direct (indirect) circulation in the jet entrance (exit) region was shifted toward the anticyclonic (cyclonic) side of the jet, so that subsidence characterized the jet core (Figure 4(b)). Such

a distribution of subsidence is consistent with that attributed to negative vorticity advection by the thermal wind, which exists along the jet axis when geostrophic cold air advection is present along a tropopause jet-front system. Subsidence through the jet core is favorable for upper-tropospheric frontogenesis, thus locally enhanced subsidence resulting from the establishment of geostrophic cold air advection along the jet (termed the Shapiro Effect) has been described as an important aspect of the upper-front life cycle. In contrast, an environment characterized by geostrophic warm air advection through the jet core shifts the thermally direct (indirect) circulation in the jet entrance (exit) region toward the cyclonic (anticyclonic) side, so that the jet core is conversely characterized by ascent (Figure 4(c)).

Figure 5 extends the Figure 4, a conceptual model to the stratospheric half of a tropopause jet-front system, where the geostrophic vertical shear and horizontal temperature gradient are reversed above the jet core, and illustrates the vertical motions forced by the idealized geostrophic stretching and shearing deformation above the level of maximum winds. An environment of pure geostrophic stretching deformation, illustrated as a straight jet streak in the absence of thermal advection, is shown in Figure 5(a). Resembling the traditional tropospheric

four-quadrant model, the thermally direct entrance region and thermally indirect exit region are evident. However, in this lower stratospheric version of the four-quadrant model, the jet entrance (exit) region ascent is located on the cyclonic (anticyclonic) shear side of the jet, opposite to its location in the corresponding environment below the jet core. Figure 5(b) shows the resulting circulations forced by geostrophic cold air advection along an idealized jet. In this case, the thermally direct (indirect) circulation shifts toward the cyclonic (anticyclonic) shear side of the entrance (exit) region. Despite this altered distribution, the same outcome is produced in the lower stratosphere as in the upper troposphere, subsidence through the local jet maximum. Finally, the case of geostrophic warm air advection along the jet is illustrated in Figure 5(c). As in the cold air advection case, though the entrance and exit region circulations shift in opposition to their counterparts below the jet core, the net result is a band of ascent through the local jet axis.

Structure and Evolution

Consideration of the lower stratospheric portion of a tropopause jet-front system as a distinct front encourages the

extension of many of the concepts of upper tropospheric frontal dynamics to regions above the level of maximum wind. The baroclinic zone located in the lower stratosphere above the jet core is best considered a frontal structure, with its own distinct frontal circulation, that separates stratospheric air from tropospheric air. Above the level of maximum winds, where the pole to equator temperature gradient reverses in accordance with thermal wind balance, the lower stratospheric front represents a boundary separating cold midlatitude upper tropospheric air from warmer midlatitude lower stratospheric air. Frontogenetic tilting across a lower stratospheric frontal zone results from a combination of subsidence maximized in the warm lower stratosphere and/or ascent maximized in the cold upper troposphere (e.g., a thermally indirect circulation). Analogous to the situation in the upper troposphere, these differential vertical motions will result in the deformation of the tropopause above the level of maximum wind, where positive tilting frontogenesis is associated with a more steeply sloped tropopause. Though the governing dynamics for their developments (tilting frontogenesis) are the same, the upper tropospheric and lower stratospheric fronts can develop asynchronously within the evolution of a tropopause jet-front system through the northwesterly and southwesterly flow portions of a baroclinic wave.

During the winter season, as a tropopause jet-front system emerges in northwesterly flow, there is a tendency for it to be characterized by a vigorous lower stratospheric frontal zone and a relatively weaker upper tropospheric frontal zone, as measured by the magnitude of the potential temperature gradients at 200 hPa (i.e., a level above the jet core) and 500 hPa (i.e., a level below the jet core), respectively. As a dynamically active tropopause jet-front system progressed through northwesterly flow, it tends to be associated with a lower stratospheric front characterized by geostrophic cold air advection in cyclonic shear (particularly in the jet entrance region). This circumstance is associated with subsidence on the cold side of the lower stratospheric frontal zone, which, in turn, decreases the intensity of the associated baroclinicity above, via tilting. This subsidence, associated with lower stratospheric frontal processes, protruded downward to sufficient depth to reach the warm side of the weak upper tropospheric front, contributing to the intensifying frontal characteristics of the attendant upper tropospheric front. Thus, forcing for subsidence within the decaying lower stratospheric frontal environment is hypothesized to be a contributing factor in an already favorable environment for the initial development of the upper tropospheric frontal portion of the tropopause jet-front system. Furthermore, as the lower stratospheric front weakens, the upper tropospheric front intensifies demonstrating a clearly asynchronous, yet dynamically interactive developmental relationship between the two component frontal zones of the tropopause jet-front system.

The evolution of lower stratospheric fronts in southwesterly flow can be notably different than their northwesterly flow counterparts. Case analyses have revealed that southwesterly flow lower stratospheric fronts tend to experience a period of intensification coincident with the weakening of their upper tropospheric counterpart. An intensifying lower stratospheric front in southwesterly flow is characterized by geostrophic warm air advection on the cyclonic shear side of the jet. Such

a circumstance promotes quasi-geostrophic conditions favorable for ascent through the jet core, which is located on the cold side of the lower stratospheric front. Such ascent is frontogenetic above the level of maximum winds, resulting in an increase of both the slope of the isentropes and the slope of the tropopause above the jet core. Ascent coincident with the lower stratospheric frontal processes is typically discernibly separate from the ascent associated with lower tropospheric frontal forcing. In special circumstances, the near-vertical superposition of a lower stratospheric front and a lower tropospheric front can create a tropospheric deep column of ascent that acts frontolytically in the middle and upper troposphere but frontogenetically in the lower stratosphere.

A conceptual model highlighting some common characteristics of northwesterly flow cases is presented in [Figure 6\(a\)](#). In northwesterly flow, the lower stratospheric frontal zone experiences frontolysis while its upper tropospheric counterpart experiences frontogenesis when the lower stratosphere in the vicinity of the tropopause jet-front system is characterized by geostrophic cold air advection in cyclonic shear. Attendant with the upper tropospheric frontogenesis is an extrusion of stratospheric PV and O₃ into the upper troposphere. The extruded stratospheric PV is manifest as an upper tropospheric absolute vorticity maximum that can serve as a precursor to surface cyclogenesis. Conversely, in southwesterly flow characterized by lower stratospheric geostrophic warm air advection in cyclonic shear, the upper tropospheric frontal zone weakens while its lower stratospheric counterpart intensifies via quasi-geostrophic ascent through the jet core ([Figure 6\(b\)](#)). As a result, it is hypothesized that tropospheric water vapor can be exported into the midlatitude lower stratosphere and low values of PV, from the lower troposphere, flood the upper troposphere/lower stratosphere on the anticyclonic shear side of a strengthening southwesterly jet. This process can lead to the amplification of the ridge at upper tropospheric levels and to anticyclogenesis in the lower troposphere downstream of the intensified jet.

It strongly suggests that consideration of the separate evolution of the lower stratospheric and upper tropospheric frontal zones associated with a tropopause jet-front system can lead to a better understanding of the comprehensive life cycle of a tropopause jet-front system through a baroclinic wave. It is left to future research to investigate how lower stratospheric frontal processes are explicitly connected to upstream or downstream sensible weather. For example, it has been hypothesized that lower stratospheric geostrophic warm air advection in cyclonic shear consistently tied to ridge building and blocking, in the way that geostrophic cold air advection in the cyclonic shear within an upper tropospheric front (e.g., the Shapiro Effect) is tied to upper-level trough and cyclone development.

The Role of Tropospheric Latent Heating in Lower Stratospheric Frontogenesis

Associated with their position in a baroclinic wave, there is a tendency for the near-superposition of southwesterly flow lower stratospheric fronts and the lower tropospheric/surface fronts associated with mature or occluded midlatitude cyclones. When the superposition of these two distinctly

Figure 6 A conceptual model of the evolution of a tropopause jet-front system in the northwesterly (a) and southwesterly (b) flow portions of a baroclinic wave, see text for details. Reproduced with permission from Lang, A.A., Martin, J.E., 2012. The structure and evolution of lower stratospheric frontal zones. Part I: Examples in northwesterly and southwesterly flow. Quarterly Journal of the Royal Meteorological Society 138, 1350–1365.

separate fronts occurs, the lower tropospheric/surface front has the potential to impact lower stratospheric frontogenesis via diabatic processes. In such a situation, the diabatic impact resulting from tropospheric frontal ascent and/or convection ahead of a surface front (e.g., reduced upper tropospheric static stability) is positioned so as to favor a robust response to lower stratospheric frontogenetic processes promoting ascent on the cold side of the lower stratospheric frontal zone.

Similarly, to the extent that lower stratospheric and lower tropospheric frontal circulations are vertically aligned, the kinetic energy released in any convective or nonconvective ascent along the tropospheric front can enhance the effect of

the frontogenetic tilting already present in the lower stratospheric frontal circulation. Latent heat release can further increase the slope of the dynamic tropopause associated with an already intensifying lower stratospheric front. In such cases, the diabatically generated outflow from latent heat release in regions of vigorous or persistent ascent, proximate to a tropopause jet-front system, produces a reduction in static stability in the vicinity of the jet core. This reduction in static stability is associated with a robust response from the dynamically forced frontal circulations in the vicinity of the extratropical tropopause and the lower stratospheric front. Cases of this sort tend to occur upstream of intensifying surface high-pressure system

and within southwesterly flow at upper levels. Consistent with a steepening tropopause, the horizontal PV gradient in the vicinity of the jet also intensified, having substantial implications on the strength of the midlatitude Rossby waveguide. Thus, the dynamics of the lower stratospheric front are influential in the sensible weather experienced at the surface, as they are intimately involved in shaping the structure of the tropopause and the midlatitude Rossby waveguide.

This coupling between the lower tropospheric and lower stratospheric processes is conceptually illustrated in Figure 7 and summarized below. As latent heat release associated with ascent linked to a lower tropospheric/surface frontal boundary reconfigures the potential temperature field within the upper troposphere, the static stability of the near-tropopause upper troposphere decreases. Such a distribution of the diabatic static stability tendency directly influences the magnitude of the quasi-geostrophic ascent on the cold side of the lower stratospheric front. The ascent that responds to the quasi-geostrophic processes, subsequently contributes to the intensification of a robust lower stratospheric front, and a notable steepening of the tropopause above the jet core, via tilting frontogenesis. In the southwesterly flow portion of a baroclinic wave, the interaction of lower tropospheric based ascent and upper tropospheric static stability is likely able to influence the development of lower stratospheric fronts and substantially alter the structure of a midlatitude jet-front system by increasing the response to lower stratospheric processes and associated ascent. Subsequently, the robust ascent maximum above the jet core can lead to an increase in the slope of not only the isentropes within the lower stratospheric front, but also the tropopause above the jet core, via tilting. When latent

heat release occurs in the vicinity of a tropopause jet-front with a dynamically active lower stratospheric front, the lower stratospheric frontal circulation may be able to enhance the mesoscale structure of the horizontal PV gradient (i.e., increase the tropopause slope) above the jet core.

The interactions between lower stratospheric frontal development and the reduction of static stability produced by *in situ* latent heating along a lower tropospheric/surface frontal zones suggest that there are a variety of mechanisms whereby poorly stratified air may be delivered to the upper troposphere to similarly influence the lower stratospheric development. A particularly intriguing possibility for such delivery lies in the outflow from organized tropical convection, manifest either as tropical convective clusters, tropical plumes or tropical cyclones (TCs), which processes low PV, low static stability boundary layer air in convective updrafts and exhausts such air into the upper troposphere. If a preexisting midlatitude jet becomes juxtaposed with such outflow, the convective outflow may be linked to a period of lower stratospheric frontogenesis associated with changes in the slope of the tropopause above the jet core. Such changes, tied as they are to increases in lower stratospheric baroclinicity via tilting from a thermally indirect circulation, must also be potentially energy generating and, thus, may provide a means by which energy released in the tropical convection might be stored for subsequent release downstream in space and time. A number of studies have recently highlighted a link between the convective TC environment and associated changes in the structure of the midlatitude jet. A recent analysis illustrated that a region of diabatically reduced PV and static stability is introduced into the vicinity of the tropopause jet-front system during

Figure 7 A schematic illustration of the interaction between diabatic heating and quasi-geostrophic processes in the vicinity of a lower stratospheric front. (a) A region of geostrophic warm air advection in the vicinity of the lower stratospheric front (shaded) is associated with modest QG ascent (arrow) above the jet core ('J'). (b) When moist ascent (large arrow) along a lower tropospheric front results in a diabatic reduction in static stability in the upper troposphere (filled arrows), the response to the geostrophic warm air advection in the vicinity of the lower stratospheric front (shaded) is a region of 'enhanced' QG ascent. The robust ascent is associated with a more steeply sloped tropopause (thick line) above the jet core and an increase in wind speed within the jet. Reproduced with permission from Lang, A.A., Martin, J.E., 2013. The structure and evolution of lower stratospheric frontal zones. Part II: The influence of tropospheric convection on lower stratospheric frontal development. Quarterly Journal of the Royal Meteorological Society 139, 1798–1809.

extratropical transition (ET) of a TC and can be associated with robust vertical circulations resulting in tilting frontogenesis above the jet core, along the lower stratospheric front. In addition, the vertical circulations provide a mechanism to tilt the tropopause into a more upright orientation (e.g., enhancing the horizontal PV gradient) that subsequently altered the mesoscale structure of the extratropical tropopause jet-front system during ET. Through the lower stratospheric front pathway, a TC undergoing ET can have substantial impacts on the intensity of the midlatitude jet circulations and the mesoscale structure and slope of the tropopause above the jet core. This highlights the lower stratospheric mechanism in which a recurving TC can have implications on the large scale by restructuring the midlatitude waveguide.

The Role of the Midlatitude Lower Stratospheric Structure in Large-Scale Circulations

In the scientific literature, the importance of the lower stratospheric portions of midlatitude tropopause jet-front systems has received the majority of its research attention in so far as it is manifested in a zonally averaged sense and on seasonal timescales. In a zonally averaged perspective, the zonally averaged meridional temperature gradient in the lower stratosphere, associated with the sloping midlatitude tropopause, is coupled (via thermal wind) to the zonal mean zonal wind field at and above the tropopause. The configuration of zonal mean zonal wind field above the tropopause determines the propagation characteristics of atmospheric waves into the stratosphere. Thus, the structure of the thermal and momentum fields above the tropopause governs the large-scale stratospheric circulation and the seasonal scale stratosphere–troposphere exchange accomplished via the wave-driven Brewer–Dobson circulation. From a zonally averaged perspective, the midlatitude lower stratospheric baroclinic structure plays a large role in the general circulation.

On shorter synoptic timescales the details of the structure, evolution, and dynamics of the lower stratospheric frontal portions of individual tropopause jet-front system systems are less understood. The changes to the thermal field at and above the tropopause associated with lower stratospheric frontogenesis are also associated with variation in the

structure of the vertical shear within the lower stratosphere. Thus, fully understanding lower stratospheric frontogenesis has further implications for the coupling between the stratosphere and troposphere by potentially explaining some of the variation in the environment governing the vertical propagation of atmosphere waves. It is suggested that consideration of lower stratospheric frontal processes will provide further insight into the not yet completely understood role of synoptic-scale baroclinic waves in transmitting the downward propagating anomalies, associated with the Northern Annular Mode, from the stratosphere to the troposphere and vice versa.

Frontogenesis

DM (David) Schultz, University of Manchester, Manchester, UK

Synopsis

The expression 'frontogenesis' can be used in three ways. The first usage is colloquial, with frontogenesis used to describe the formation or intensification of a frontal zone. The second usage is mathematical, where the frontogenesis function is the Lagrangian rate of change of the potential temperature gradient. Various mathematical forms of the frontogenesis function have been developed, ranging from the simplest scalar form of the Petterssen frontogenesis to the complete scalar form of the Miller frontogenesis. Two vector forms have also been developed, those pertinent to two-dimensional flow and three-dimensional flow. Each form of the scalar or vector frontogenesis function has a different purpose. The third usage is physical, a description of the physical processes involved in creating and intensifying a front. Specifically, frontogenesis occurs as an initial large-scale geostrophic confluence or shear acts to increase the magnitude of a quasi-horizontal temperature gradient, eventually resulting in its nonlinear collapse due to the resulting ageostrophic secondary circulation.

Introduction

Frontogenesis has three common usages. The first usage is colloquial, where frontogenesis is used to describe the formation or intensification of a frontal zone. Because the primary measure of the intensity of a front is the horizontal temperature gradient, intensifying fronts are defined as those with increasing temperature gradients. The second usage is mathematical, where the frontogenesis function calculates the Lagrangian rate of change of the potential temperature gradient. The third usage is physical, where frontogenesis describes the process by which fronts intensify. Which definition of frontogenesis is being employed at any given time is usually understood from its context. In all three usages, the opposite of frontogenesis is called frontolysis, the weakening or dissipation of a front.

Colloquial Usage

The term frontogenesis, when used in the vernacular, describes the formation or intensification of a front or a frontal zone, usually measured by an increase in the horizontal temperature gradient across the frontal zone. For example, 'frontogenesis occurred along the leading edge of the arctic air mass over southern Kansas during the late afternoon on 25 October.'

To calculate the intensification of a frontal zone, the horizontal temperature gradient across the front must be measured in a reference frame moving with the front. For this reason, the mathematical form of the colloquial usage can be easily expressed, but it is difficult to calculate because a field representing the vector motion of the front is needed. Thus, developing an automated approach to measuring frontogenesis in this quasi-Lagrangian framework is rarely performed in practice (Schultz, 2007; Markowski and Stonitsch, 2007). Instead, point measurements of the temperature gradient across the front are usually computed and compared from one time to the next.

The second usage of the term frontogenesis avoids these practical difficulties, but at the expense of a direct measure of

frontal intensification. Instead, the mathematical formulation of frontogenesis in the next section becomes a kinematic description of flow patterns favorable for fronts to intensify.

Mathematical Usage

Petterssen (1936) first defined a mathematical quantity called frontogenesis involving the potential temperature gradient and the wind field. As a kinematic quantity, it is not a predictive tool to say whether a front will intensify, but merely a diagnostic one showing regions where the wind field is acting to intensify the gradient of potential temperature. Later researchers developed other forms of frontogenesis for various specialized purposes. The history and development of mathematical expressions for frontogenesis are discussed in this section.

Petterssen Frontogenesis

Petterssen (1936) defined frontogenesis F as the Lagrangian rate of change of the magnitude of the horizontal potential temperature (θ) gradient due to the horizontal wind ($\mathbf{V}_2 = u\mathbf{i} + v\mathbf{j}$):

$$F_{\text{Pet2}} = \frac{d}{dt} |\nabla_2 \theta|, \quad [1]$$

where

$$\begin{aligned} \frac{d}{dt} &= \frac{\partial}{\partial t} + u \frac{\partial}{\partial x} + v \frac{\partial}{\partial y}, \\ \nabla_2 &= \mathbf{i} \frac{\partial}{\partial x} + \mathbf{j} \frac{\partial}{\partial y}. \end{aligned}$$

Equation [1] can be written as

$$F_{\text{Pet2}} = -\frac{1}{|\nabla_2 \theta|} \left[\underbrace{\frac{\partial \theta}{\partial x} \left(\frac{\partial u}{\partial x} \frac{\partial \theta}{\partial x} + \frac{\partial u}{\partial y} \frac{\partial \theta}{\partial y} \right)}_{p_1} + \underbrace{\frac{\partial \theta}{\partial y} \left(\frac{\partial v}{\partial x} \frac{\partial \theta}{\partial x} + \frac{\partial v}{\partial y} \frac{\partial \theta}{\partial y} \right)}_{p_2} \right], \quad [2]$$

where terms p_1 and p_2 represent frontogenesis due to horizontal deformation/divergence. Petterssen (1936) showed that, if potential temperature is conserved, then the terms p_1 and p_2 can be rewritten as

$$F_{\text{Pet}2} = \frac{1}{2} |\nabla_2 \theta| \underbrace{(E \cos 2\beta)}_{\text{deformation}} - \underbrace{(\nabla_2 \cdot \mathbf{V}_2)}_{\text{divergence}}, \quad [3]$$

where β is the local angle between an isentrope and the axis of dilatation. The resultant deformation E is $(E_{\text{st}}^2 + E_{\text{sh}}^2)^{1/2}$, where $E_{\text{st}} = \partial u/\partial x - \partial v/\partial y$ is the stretching deformation and $E_{\text{sh}} = \partial v/\partial x + \partial u/\partial y$ is the shearing deformation. Frontogenesis in eqn [3] consists of two terms. The first term is proportional to the resultant deformation, and the second term is proportional to the horizontal divergence. Deformation acting on a horizontal temperature gradient will increase the gradient if the angle between the isentrope and the axis of dilatation is less than 45° . Deformation acting on a horizontal temperature gradient will decrease the gradient if the angle between the isentrope and the axis of dilatation is greater than 45° . Convergence acting on a horizontal temperature gradient will increase the gradient, and divergence will decrease the gradient.

Equation [3] is referred to as the *Petterssen frontogenesis function*, or simply *Petterssen frontogenesis*. Petterssen frontogenesis is the most commonly used mathematical form of frontogenesis. If the flow is geostrophic, then the divergence term in eqn [3] is zero because the geostrophic wind on an f -plane is nondivergent. Consequently, the frontogenesis due to the geostrophic wind is a result of the deformation only. If the geostrophic wind is used in eqn [3], then Keyser et al. (1988) showed that Petterssen frontogenesis is related to the forcing for quasigeostrophic vertical velocity associated with the divergence of the component of the $\mathbf{Q}$ -vector normal to the isentropes. Ascent will occur on the warm side of a region of positive Petterssen frontogenesis and descent will occur on the cool side of a region of positive Petterssen frontogenesis. Because Petterssen frontogenesis does not consider vertical velocities, it is most appropriate for use at the surface where the vertical velocity is zero. Consequently, the most common uses of Petterssen frontogenesis are to (1) examine the contributions of the total horizontal wind to changing the thermal gradient and (2) estimate the location of the secondary circulation (more on this later). Forms of the Petterssen frontogenesis function have been used to link frontogenesis to heavy rains (Sanders, 2000), elevated convective winter storms (Trapp et al., 2001), and fronts discretely propagating through the Intermountain West (Steenburgh et al., 2009). Other practical uses include an objective method for identifying the locations of fronts (Schultz, 2004; Kemppi and Sinclair, 2011) or determining the time of extratropical transition of a tropical cyclone (Harr and Elsberry, 2000).

Petterssen Frontogenesis for Three-Dimensional Flow

Because Petterssen frontogenesis does not include vertical velocity, this form of frontogenesis is generally inappropriate for application to fronts above the surface. Horizontal gradients in vertical velocity can be crucial to frontogenesis above

the surface, particularly upper-level frontogenesis occurring at the tropopause. To account for this effect, Petterssen frontogenesis can be reformulated to account for horizontal gradients of vertical motion that lead to tilting of isentropes in the vertical and that produce horizontal temperature gradients.

$$F_{\text{Pet}3} = \frac{d}{dt} |\nabla_2 \theta|, \quad [4]$$

where $\mathbf{V}_3 = (u, v, w)$ is the total velocity and

$$\frac{d}{dt} = \frac{\partial}{\partial t} + u \frac{\partial}{\partial x} + v \frac{\partial}{\partial y} + w \frac{\partial}{\partial z}.$$

Equation [4] can be written as

$$F_{\text{Pet}3} = -\frac{1}{|\nabla_2 \theta|} \left[\underbrace{\frac{\partial \theta}{\partial x} \left(\frac{\partial u}{\partial x} \frac{\partial \theta}{\partial x} + \frac{\partial u}{\partial y} \frac{\partial \theta}{\partial y} \right)}_{p_1} + \underbrace{\frac{\partial \theta}{\partial y} \left(\frac{\partial v}{\partial x} \frac{\partial \theta}{\partial x} + \frac{\partial v}{\partial y} \frac{\partial \theta}{\partial y} \right)}_{p_2} + \underbrace{\frac{\partial \theta}{\partial z} \left(\frac{\partial w}{\partial x} \frac{\partial \theta}{\partial x} + \frac{\partial w}{\partial y} \frac{\partial \theta}{\partial y} \right)}_{p_3} \right], \quad [5]$$

where terms p_1 and p_2 represent frontogenesis due to horizontal deformation/divergence and the term p_3 represents frontogenesis due to tilting of isentropes by horizontal gradients in vertical velocity. The sum of the horizontal frontogenesis terms p_1 and p_2 in eqn [5] also can be expressed as Petterssen frontogenesis.

The term p_3 represents tilting frontogenesis due to vertical-velocity gradients acting on the quasi-horizontal potential temperature gradient. The term p_3 can also be expressed as

$$p_3 = -\frac{\partial \theta}{\partial z} (\nabla_2 w \cdot \nabla_2 \theta) = -\frac{\partial \theta}{\partial z} \left(\frac{\partial w}{\partial n} \right), \quad [6]$$

such that

$$F = \frac{1}{2} |\nabla_2 \theta| (E \cos 2\beta - \nabla_2 \cdot \mathbf{V}_2) - \frac{1}{|\nabla_2 \theta|} \frac{\partial \theta}{\partial z} (\nabla_2 w \cdot \nabla_2 \theta). \quad [7]$$

This form was developed by Schultz and Steenburgh (1999) to explore the importance of the vertical motion toward changing the horizontal thermal gradient in a case of a forward tilted front during the Superstorm of March 1993. Because this form of frontogenesis already includes the vertical velocity, this form should not be used to examine the forcing for the secondary circulation.

Early forms of the three-dimensional Petterssen frontogenesis include Reed and Sanders (1953), Sanders (1955), and Ogura and Portis (1982) who first showed the kinematic processes acting on fronts. Using a model simulation of the Sanders (1955) cold front, Schultz and Roebber (2008) calculated the terms in this form of frontogenesis to reexamine the processes favoring frontogenesis. Because the isentropes were steeply sloped at the leading edge of the front, Schultz and Roebber (2008) concluded that tilting frontogenesis was negligible, contrary to the original results of Sanders (1955).

Miller (1948) Three-Dimensional Frontogenesis

A further generalization is to include the magnitude of the three-dimensional potential temperature gradient, leading to the Miller (1948) form of frontogenesis. Miller frontogenesis explains the time rate of change of the three-dimensional potential temperature gradient following air parcel motion in three dimensions. Miller (1948) extended Petterssen's definition to fronts in the free atmosphere by developing an equation for the changes of the *three-dimensional* gradient of the potential temperature due to the three-dimensional wind:

$$F_{\text{Miller}} = \frac{d}{dt} |\nabla_3 \theta|, \quad [8]$$

where

$$\begin{aligned} \frac{d}{dt} &= \frac{\partial}{\partial t} + u \frac{\partial}{\partial x} + v \frac{\partial}{\partial y} + w \frac{\partial}{\partial z}, \\ \nabla_3 &= \mathbf{i} \frac{\partial}{\partial x} + \mathbf{j} \frac{\partial}{\partial y} + \mathbf{k} \frac{\partial}{\partial z}. \end{aligned}$$

$$F_{\text{Miller}} = -\frac{1}{|\nabla_3 \theta|} \times \left[\frac{\partial \theta}{\partial x} \left(\underbrace{\frac{\partial u}{\partial x} \frac{\partial \theta}{\partial x}}_1 + \underbrace{\frac{\partial v}{\partial x} \frac{\partial \theta}{\partial y}}_2 + \underbrace{\frac{\partial w}{\partial x} \frac{\partial \theta}{\partial z}}_3 \right) + \frac{\partial \theta}{\partial y} \left(\underbrace{\frac{\partial u}{\partial y} \frac{\partial \theta}{\partial x}}_4 + \underbrace{\frac{\partial v}{\partial y} \frac{\partial \theta}{\partial y}}_5 + \underbrace{\frac{\partial w}{\partial y} \frac{\partial \theta}{\partial z}}_6 \right) + \frac{\partial \theta}{\partial z} \left(\underbrace{\frac{\partial u}{\partial z} \frac{\partial \theta}{\partial x}}_7 + \underbrace{\frac{\partial v}{\partial z} \frac{\partial \theta}{\partial y}}_8 + \underbrace{\frac{\partial w}{\partial z} \frac{\partial \theta}{\partial z}}_9 \right) \right].$$

Terms 1, 2, 4, and 5 are the horizontal-deformation terms; 7 and 8 are the vertical-deformation terms; 3 and 6 are the tilting terms (as shown in the previous section); term 9 is the vertical divergence term (recall that $\partial w / \partial z = \nabla_2 \cdot \mathbf{V}_2$).

The terms in the Miller frontogenesis comprise two groups: one for the horizontal potential temperature gradient (terms 1–6), comparable to the Petterssen frontogenesis with tilting (5), and one for the vertical potential temperature gradient (terms 7–9). Given that the vertical potential temperature gradient is the dry static stability $\partial \theta / \partial z$, the second group represents the physical processes responsible for static stability increasing or decreasing (Bosart, 1970).

$$\frac{d}{dt} \left(\frac{\partial \theta}{\partial z} \right) = -\frac{1}{|\nabla_3 \theta|} \frac{\partial \theta}{\partial z} \left(\underbrace{\frac{\partial u}{\partial z} \frac{\partial \theta}{\partial x}}_7 + \underbrace{\frac{\partial v}{\partial z} \frac{\partial \theta}{\partial y}}_8 + \underbrace{\frac{\partial w}{\partial z} \frac{\partial \theta}{\partial z}}_9 \right). \quad [9]$$

Because vertical gradients of potential temperature are an order or two larger than horizontal gradients of potential temperature, these terms dominate the frontogenesis calculation. Consequently, for some applications, separating the horizontal terms (Petterssen frontogenesis with tilting) from the vertical terms (stability frontogenesis) may be a fruitful way to analyze the

frontogenesis, neglecting the difference between $\nabla_2 \theta$ and $\nabla_3 \theta$ in the denominator. For this reason, the complete form of Miller frontogenesis is rarely used in the meteorological literature.

Vector Frontogenesis: Keyser et al. (1988)

Until this point, frontogenesis has been considered to be a scalar quantity related to the magnitude of the potential temperature gradient. Yet, the potential temperature gradient is a vector, so its direction may also be relevant. Consequently, a form of frontogenesis can be written to treat frontogenesis as a vector. Written in this manner, frontogenesis is a vector with a component normal to the isentropes and a component along the isentropes. Keyser et al. (1988) showed that the Petterssen form of frontogenesis could be generalized to a vector form where

$$\mathbf{F}_2 = \frac{d}{dt} \nabla_2 \theta, \quad [10]$$

where

$$\frac{d}{dt} = \frac{\partial}{\partial t} + u \frac{\partial}{\partial x} + v \frac{\partial}{\partial y}.$$

Resolving $\mathbf{F}_2$ into natural coordinates (s, n) such that the s axis is locally tangent to an isentrope and the n axis points toward colder air on a constant pressure surface (i.e., $\mathbf{s}$ points in the same direction as the thermal wind):

$$\frac{d}{dt} \nabla_2 \theta = \mathbf{n} \left(\mathbf{n} \cdot \frac{d}{dt} \nabla_2 \theta \right) + \mathbf{s} \left(\mathbf{s} \cdot \frac{d}{dt} \nabla_2 \theta \right), \quad [11]$$

where

$$\mathbf{n} = -\frac{\nabla_2 \theta}{|\nabla_2 \theta|}, \quad [12a]$$

$$\mathbf{s} = \mathbf{n} \times \mathbf{k}. \quad [12b]$$

Equation [10] becomes

$$\mathbf{F}_2 = F_{2n} \mathbf{n} + F_{2s} \mathbf{s}, \quad [13]$$

where F_{2n} is referred to as the scalar frontogenesis and F_{2s} is referred to as the rotational frontogenesis (Keyser et al., 1988, eqns [2.3a] and [2.3b]):

$$F_{2n} = -\frac{d}{dt} |\nabla_2 \theta|, \quad [14a]$$

$$F_{2s} = \mathbf{n} \cdot \left(\mathbf{k} \times \frac{d}{dt} \nabla_2 \theta \right). \quad [14b]$$

Therefore, positive F_{2n} implies frontolysis (note the negative sign), whereas positive F_{2s} implies cyclonic rotation of the isentropes.

Development of these expressions results in

$$F_{2n} = -\frac{1}{|\nabla_2 \theta|} \left\{ \underbrace{\frac{\partial \theta}{\partial x} \left(-\frac{\partial u}{\partial x} \frac{\partial \theta}{\partial x} - \frac{\partial v}{\partial x} \frac{\partial \theta}{\partial y} \right)}_{n_1} + \underbrace{\frac{\partial \theta}{\partial y} \left(-\frac{\partial u}{\partial y} \frac{\partial \theta}{\partial x} - \frac{\partial v}{\partial y} \frac{\partial \theta}{\partial y} \right)}_{n_2} \right\}, \quad [15a]$$

$$F_{2s} = -\frac{1}{|\nabla_2\theta|} \left\{ \underbrace{\frac{\partial\theta}{\partial y} \left(-\frac{\partial u}{\partial x} \frac{\partial\theta}{\partial x} - \frac{\partial v}{\partial x} \frac{\partial\theta}{\partial y} \right)}_{s_1} - \underbrace{\frac{\partial\theta}{\partial x} \left(-\frac{\partial u}{\partial y} \frac{\partial\theta}{\partial x} - \frac{\partial v}{\partial y} \frac{\partial\theta}{\partial y} \right)}_{s_2} \right\}. \quad [15b]$$

Following Keyser et al. (1988: pp. 764–765), expressions similar to their eqns [2.10a] and [2.10b] result in

$$F_{2n} = \frac{1}{2} |\nabla_2\theta| (\nabla_2 \cdot \mathbf{V}_2 - E \cos 2\beta) \quad [16a]$$

$$F_{2s} = \frac{1}{2} |\nabla_2\theta| (\mathbf{k} \cdot \nabla_2 \times \mathbf{V}_2 + E \sin 2\beta). \quad [16b]$$

This expression for F_{2n} (eqn [16a]) comprises two terms related to divergence and deformation (as before), whereas the expression for F_{2s} (eqn [16b]) comprises two terms related to relative vorticity and deformation.

Vector Frontogenesis, Including Vertical Motion Terms

Since contributions from vertical motion are typically small for surface fronts, but not necessarily so for upper-level fronts where tilting may be important, Keyser et al.'s (1988) methodology can be extended to include the frontogenetical effects due to vertical motion (Schultz and Doswell, 1999). Therefore, in this section, we define vector frontogenesis, F_3 , as the Lagrangian rate of change of the magnitude and direction of the horizontal potential temperature gradient due to the three-dimensional wind:

$$\mathbf{F}_3 = \frac{d}{dt} \nabla_2\theta, \quad [17]$$

where

$$\frac{d}{dt} = \frac{\partial}{\partial t} + u \frac{\partial}{\partial x} + v \frac{\partial}{\partial y} + w \frac{\partial}{\partial z}.$$

This results in the following expressions:

$$F_{3n} = -\frac{1}{|\nabla_2\theta|} \left\{ \underbrace{\frac{\partial\theta}{\partial x} \left(-\frac{\partial u}{\partial x} \frac{\partial\theta}{\partial x} - \frac{\partial v}{\partial x} \frac{\partial\theta}{\partial y} \right)}_{n_1} + \underbrace{\frac{\partial\theta}{\partial y} \left(-\frac{\partial u}{\partial y} \frac{\partial\theta}{\partial x} - \frac{\partial v}{\partial y} \frac{\partial\theta}{\partial y} \right)}_{n_2} + \underbrace{\frac{\partial\theta}{\partial z} \left(-\frac{\partial w}{\partial x} \frac{\partial\theta}{\partial x} - \frac{\partial w}{\partial y} \frac{\partial\theta}{\partial y} \right)}_{n_3} \right\}, \quad [18a]$$

$$F_{3s} = -\frac{1}{|\nabla_2\theta|} \left\{ \underbrace{\frac{\partial\theta}{\partial y} \left(-\frac{\partial u}{\partial x} \frac{\partial\theta}{\partial x} - \frac{\partial v}{\partial x} \frac{\partial\theta}{\partial y} \right)}_{s_1} - \underbrace{\frac{\partial\theta}{\partial x} \left(-\frac{\partial u}{\partial y} \frac{\partial\theta}{\partial x} - \frac{\partial v}{\partial y} \frac{\partial\theta}{\partial y} \right)}_{s_2} + \underbrace{\frac{\partial\theta}{\partial z} \left(-\frac{\partial w}{\partial y} \frac{\partial\theta}{\partial x} - \frac{\partial w}{\partial x} \frac{\partial\theta}{\partial y} \right)}_{s_3} \right\}. \quad [18b]$$

Terms n_1 , n_2 , s_1 , and s_2 represent similar terms in eqns [15a] and [15b]. The term n_3 represents tilting scalar frontogenesis due to vertical-velocity gradients across the horizontal potential temperature gradient and the term s_3 represents tilting rotational frontogenesis due to vertical-velocity gradients across the horizontal potential temperature gradient.

Following Keyser et al. (1988: pp. 764–765), expressions similar to their eqns [2.10a] and [2.10b] can be derived:

$$F_{3n} = \frac{1}{2} |\nabla_H\theta| (\nabla_H \cdot \mathbf{V}_H - E \cos 2\beta) + \frac{1}{|\nabla_H\theta|} \frac{\partial\theta}{\partial p} (\nabla_H\omega \cdot \nabla_H\theta), \quad [19a]$$

$$F_{3s} = \frac{1}{2} |\nabla_H\theta| (\mathbf{k} \cdot \nabla_H \times \mathbf{V}_H + E \sin 2\beta) + \frac{1}{|\nabla_H\theta|} \frac{\partial\theta}{\partial p} \mathbf{k} \cdot (\nabla_H\omega \times \nabla_H\theta). \quad [19b]$$

This expression for F_{3n} (eqn [19a]) comprises three terms related to divergence, deformation, and tilting, whereas (eqn [19b]) for F_{3s} comprises three terms related to relative vorticity, deformation, and tilting.

Equations [19a] and [19b] correct typographical errors in eqns [11a] and [11b] in Schultz and Doswell (1999), as documented in Schultz (2013).

Equations [19a] and [19b] were used by Schultz and Doswell (1999) to investigate the physical processes that lead to upper-level frontogenesis. They found that the onset of cold advection often observed at the leading edge of upper-level fronts was associated with the rotational frontogenesis in that region.

Other Forms

The most general form of the frontogenesis function would be an expression for vector frontogenesis using the full three-dimensional potential temperature gradient. What value such an expression would have for understanding fronts or calculating frontogenesis is not immediately apparent. Specifically, as of the writing of this article, vector frontogenesis expansions for three-dimensional Miller frontogenesis have not been constructed. Even if they were, how they would be used in operational weather forecasting or research is not clear.

Physical Usage

The physical usage of the term frontogenesis refers to the physical processes responsible for increasing the temperature gradient associated with a frontal zone. Specifically, many fronts are formed in a region where large-scale deformation occurs, differentially advecting isentropes and increasing the horizontal temperature gradient. Hoskins and Bretherton (1972) demonstrated that frontogenesis proceeds in two steps. In the first step, large-scale geostrophic deformation increases the horizontal temperature gradient. If that were the only frontogenetical process, having a front reach a first-order discontinuity in temperature gradient (discontinuous in potential temperature gradient), as is observed in many well-developed fronts, would take an infinite time. Sanders (2000) showed this by simplifying the Miller form of the frontogenesis function:

$$\frac{d}{dt} \{\ln(-\partial\theta/\partial y)\} = -\partial v/\partial y. \quad [20]$$

The logarithmic relationship between the deformation and the temperature gradient implies that it will take an infinitely long time for a first-order discontinuity to be reached. For this reason, geostrophic deformation by itself is insufficient to produce realistic fronts.

To produce realistic fronts, the second step is required. As the temperature gradient increases, a secondary ageostrophic circulation develops to maintain thermal wind balance. Ascending air on the warm side of the front cools adiabatically and descending air on the cold side of the front warms adiabatically, reducing the temperature gradient across the front. The resulting horizontal branches of the circulation, required to maintain continuity, are torqued by the Coriolis force, increasing the vertical wind shear across the front and leading to contraction of the horizontal temperature gradient in a finite time. These two components of the secondary circulation help to maintain thermal wind balance across the front, in the face of increasing thermal gradients. Mathematically, this secondary circulation can be expressed through the Sawyer–Eliassen equation (Sawyer, 1956; Eliassen, 1962, 1990).

Sawyer–Eliassen Equation

If the atmosphere is hydrostatic, then the adiabatic Sawyer–Eliassen equation can be derived for the resulting circulation in the cross-frontal (y - z) plane:

$$N^2 \frac{\partial^2 \psi}{\partial y^2} + 2S^2 \frac{\partial^2 \psi}{\partial y \partial z} + F^2 \frac{\partial^2 \psi}{\partial z^2} = 2Q_2, \quad [21]$$

where ψ is the ageostrophic streamfunction in the y - z plane

$$v_{ag} = -\frac{\partial \psi}{\partial z},$$

$$w = \frac{\partial \psi}{\partial y},$$

and terms

$$N^2 = \frac{\partial b}{\partial z},$$

$$S^2 = -\frac{\partial b}{\partial y} = f \frac{\partial u_g}{\partial z},$$

and

$$F^2 = f \left(f - \frac{\partial u_g}{\partial y} \right)$$

represent the static stability, baroclinic stability, and inertial stability. The two terms in Q_2 (often called the forcing terms) represent the geostrophic stretching and geostrophic shearing contributions to frontogenesis.

$$Q_2 = f \left(\frac{\partial v_g}{\partial y} \frac{\partial u_g}{\partial z} - \frac{\partial u_g}{\partial y} \frac{\partial v_g}{\partial z} \right). \quad [22]$$

When these terms are negative, frontogenesis occurs and is associated with a balanced direct secondary circulation. The shape of the circulation depends upon the static, baroclinic and inertial stabilities (Hakim and Keyser, 2001).

The Sawyer–Eliassen equation can be solved if the potential vorticity q is positive, producing an elliptic equation, and appropriate boundary conditions are specified.

$$q = N^2 F^2 - S^4 > 0. \quad [23]$$

The condition for positive potential vorticity is equivalent to the criterion for symmetric stability.

Summary

Three definitions of frontogenesis are in common use today. The first is a vernacular expression to describe the intensification of a front. Although a mathematical expression can be derived, in principle, its calculation is not so simple.

The second definition is a mathematical one, related specifically to the Lagrangian time rate of change of the potential temperature gradient. Although various forms of the mathematical expression for frontogenesis can be derived, which form is needed will depend upon a given circumstance. To qualitatively represent the region of frontal forcing for ascent for a surface front or to produce a surface field indicating where horizontal temperature gradients are strengthening, Petterssen frontogenesis will suffice. Above the surface, three-dimensional terms must be included. Finally, because the temperature gradient is a vector, an expression for vector frontogenesis can also be derived.

The third definition is a process-based definition: the physical processes producing an intensifying frontal zone. The process of frontogenesis proceeds in two steps: the large-scale geostrophic deformation, followed by the secondary circulation further contracting the frontal zone and acting to maintain thermal wind balance.

Introduction

Jet streaks, defined as localized wind speed maxima along the axis of a jet stream, are generally found in association with frontal zones in the upper troposphere, and together these features are often referred to as 'jet-front systems.' In many cases, jet streaks are also accompanied by a localized downward intrusion of air from the stratosphere into the troposphere known as a 'tropopause fold.' The interest that jet streaks have attracted in the fields of synoptic and dynamic meteorology stems from their importance in the development and behavior of synoptic-scale and mesoscale weather systems, including extratropical cyclones and mesoscale convective systems. In addition to their association with these weather systems, jet streaks are often implicated with other phenomena and processes of interest to atmospheric science, such as clear air turbulence, stratosphere–troposphere exchange, and a class of motions referred to as 'unbalanced' (e.g., inertial and buoyancy oscillations). The basic structure of jet streaks and the role that these features play in the evolution of extratropical cyclones and of mesoscale convective systems are often portrayed schematically in terms of conceptual models that relate jet streaks in various flow configurations to characteristic patterns of horizontal divergence and vertical motion. Dynamical interpretation of jet streaks has proceeded along two lines of thinking: in the first, referred to as 'balanced,' it is assumed that a dynamical relationship constrains the wind and geopotential fields; in the second, referred to as 'unbalanced,' no such constraint exists. In the balanced case, jet streaks may be interpreted either as an integral part of upper-tropospheric baroclinic waves, in which case their evolution is controlled by energy dispersion associated with the wave, or in terms of the interaction between coherent vortices and the jet stream, in which case their evolution occurs in response to the motion and evolution of the constituent vortices. In the unbalanced case, the dynamics are strongly coupled to a category of buoyancy oscillations referred to as inertia-gravity waves, which may strongly modulate weather systems on short time scales.

General Characteristics of Jet Streaks

Jet streaks are observed along the polar-front and subtropical jet streams in both the Northern and Southern Hemispheres and can be either mobile or stationary with respect to the stream in which they are embedded. Like atmospheric fronts, to which they are closely related, jet streaks are often significantly anisotropic, exhibiting disparate length scales in the along-jet and cross-jet directions, with the former being up to an order of magnitude larger than the latter. In the case of the polar-front jet stream, jet streaks typically have length scales of 2000 km or less in the along-jet direction and progress

eastward through the meanders of the stream. Some polar-front jet streaks are observed to translate continuously along the jet stream, whereas others travel discretely and appear to jump between the north-westerly and south-westerly flow inflections of the wave pattern in the stream. In the case of the subtropical jet stream, jet streaks possess along-jet length scales of 4000–8000 km and tend to be approximately stationary and located in the ridges of the wavelike meanders in the stream.

Jet streaks often play a critical role in the development of extratropical cyclones and in the organization of mesoscale convective systems, and as such have become an important part of mainstream synoptic meteorology and weather forecasting. The association of jet streaks with these phenomena is related to the observation that the divergence of the horizontal wind (hereafter, this quantity will be referred to as the horizontal divergence, while the terms divergence and convergence will be used to distinguish between positive and negative values of this quantity, respectively) is frequently large in the vicinity of jet streaks. The relationship of horizontal divergence in the upper troposphere to changes in sea level pressure and to patterns of vertical motion in the middle troposphere is well known. Indeed, a fundamental principle of early synoptic meteorology states that the development of surface cyclones requires upper-level divergence slightly in excess of lower-level convergence, which results in a net reduction in mass in the column and a decrease in the sea level pressure. The vertical circulations associated with patterns of horizontal divergence in the upper troposphere may be inferred using the equation of mass continuity formulated in pressure coordinates, given by $\nabla \cdot \mathbf{V} = -\partial\omega/\partial p$, where ∇ is the horizontal gradient operator evaluated on an isobaric surface, $\mathbf{V}$ is the horizontal wind velocity, and ω is the vertical velocity in pressure coordinates. The pressure-coordinate vertical velocity is related approximately to the height-coordinate vertical velocity, w , via $\omega \approx -\rho gw$, where ρ is air density, g is the acceleration due to gravity, and positive (negative) ω corresponds to downward (upward) motion. The pressure-coordinate form of the vertical velocity is adopted for the remainder of this article. Since the vertical velocity is generally close to zero near the tropopause, divergence (convergence) in the upper troposphere will be associated with ascending (descending) motion in the middle troposphere. This relationship between upper-tropospheric horizontal divergence and middle-tropospheric vertical motion will be alluded to frequently in the remainder of this article.

Although the observed structure and behavior of jet streaks can vary considerably from case to case, several properties are common to these features and are illustrated through the analysis of a jet streak observed over the north central United States on 3 November 1995. In [Figure 1](#), which depicts the wind speed and geopotential height fields at 300 hPa, the jet streak is located in the south-westerly flow inflection of a synoptic-scale trough–ridge pattern. In this jet streak, the

Figure 1 European Centre of Medium-Range Weather Forecasts (ECMWF) analysis on the 300 hPa pressure surface, valid at 1200 UTC 3 November 1995, depicting wind speed (values greater than 50 m s^{-1} shaded as indicated) and geopotential height (contour interval 120 m; solid lines).

maximum wind speed is approximately 75 m s^{-1} , and the aspect ratio expressed in terms of along-jet to cross-jet length scales is approximately 4:1 as determined by the configuration of the 60 m s^{-1} isotach.

A vertical cross-section through the jet streak under consideration in the cross-jet direction is shown in **Figure 2**, which illustrates the components of a jet-front system. The tropopause, depicted as the thick solid line, is defined 'dynamically' as the 2 PVU potential vorticity surface ($1 \text{ PVU} = 10^{-6} \text{ m}^2 \text{ s}^{-1} \text{ K kg}^{-1}$). Here potential vorticity, P , is given by $P = -g(\partial\theta/\partial p)(f + \zeta_\theta)$, where f is the Coriolis parameter, θ is the potential temperature, and ζ_θ is the vertical component of the relative vorticity evaluated on an isentropic surface. In the vicinity of the jet streak, the tropopause transects the core of maximum wind speed (i.e., the 'jet core') and slopes steeply, being considerably lower on the poleward side than on the equatorward side. The downward and equatorward protrusion of the tropopause into the middle troposphere beneath the jet streak corresponds to an incipient tropopause fold. In a well-developed fold, the tropopause generally exhibits an S-shaped pattern, such that there is a significant region in which the tropopause height is multivalued. Above the jet core, the contours of constant potential temperature (i.e., isentropes) slope upward. Below the jet core, the isentropes slope downward, such that the potential temperature gradient evaluated on an isobaric surface in this region is locally large. This area of locally enhanced horizontal potential temperature gradient defines the upper-tropospheric frontal zone, which in this case extends well into the middle troposphere and joins with the upward extension of a surface frontal zone. The fan-shaped pattern of the isentropes observed in conjunction with this jet streak is a consequence of the thermal

wind relation, which links the vertical shear of the geostrophic wind to the horizontal potential temperature gradient.

Jet streaks in the upper troposphere and their associated frontal zones can also be preferred locations for phenomena not normally thought of as related to weather. In the regions of large vertical shear above and below the jet streak, the Richardson number, Ri , defined as $Ri = (g/\theta)(\partial\theta/\partial z)/|\partial\mathbf{V}/\partial z|^2$, can become small. When this is the case, the flow can break down into turbulent eddies. Since this breakdown often occurs in regions of background subsidence and relatively cloud-free air, this phenomenon is generally referred to as 'clear air turbulence,' which can be hazardous to aircraft. Moreover, the region of turbulent mixing tends to be localized in the vicinity of the tropopause fold, which contains stratospheric air protruding downwards into the troposphere. In the region of mixing, the tropopause, which ordinarily corresponds to a material surface separating stratospheric from tropospheric air, is highly porous, allowing for a vigorous two-way exchange of air and trace constituents between the stratosphere and troposphere.

The applicability of the thermal wind relation referred to above to jet-front systems implies the validity of geostrophic balance, which will now be employed in considering the dynamics of jet streaks. Geostrophic balance is valid to a first approximation in many jet streaks, such that the so-called ageostrophic wind (defined as $\mathbf{V}_{ag} = \mathbf{V} - \mathbf{V}_g$, the vector difference between the actual horizontal wind and the geostrophic wind) is relatively small in comparison to the geostrophic wind. The magnitude of the departure from geostrophic balance is quantified by the Rossby number, Ro , which is defined as the ratio of the characteristic scales for the velocity acceleration and the Coriolis force, and is given by $Ro = V/fL$, where L and V

Figure 2 Cross-section along A–A' indicated in [Figure 1](#), valid at 1200 UTC 3 November 1995, depicting wind speed normal to the plane of the section (values greater than 50 m s^{-1} shaded as indicated), potential temperature (contour interval 4 K; thin solid lines) and the dynamic tropopause (thick solid line).

may be taken to be the along-jet length scale and the maximum wind speed of the jet streak, respectively. If Ro is small with respect to unity, the jet streak will be in approximate geostrophic balance. In such cases the so-called quasi-geostrophic system, an approximation to the full equations of motion valid for small Ro , provides a useful foundation for understanding the structure and behavior of jet streaks. In fact, the quasi-geostrophic system often is applicable under circumstances beyond the limits of its strict validity, so that it may be employed qualitatively to interpret the structure and behavior of jet streaks in which Ro is not particularly small. Many of the existing dynamical concepts regarding jet streaks are based on deductions derived from the quasi-geostrophic system. Nevertheless, sometimes Ro can be so large in the vicinity of jet streaks that the quasi-geostrophic system is not even qualitatively useful. In such jet streaks, unbalanced motions may be important to the evolution of the streak and the full equations of motion, also known as the primitive equations, are required to elucidate the properties of the flow and the behavior of the streak.

The ageostrophic wind at 300 hPa for the jet streak under consideration, shown in [Figure 3](#), displays a four-gyre circulation pattern that is cyclonic upstream and downstream of the jet core and anticyclonic on the flanks of the streak. Hence, in the region upstream of the jet core, known as the entrance region, the ageostrophic wind is directed toward the poleward (i.e., cyclonic-shear) side of the streak, corresponding to lower geopotential height; in the region downstream of the jet core, known as the exit region, the ageostrophic wind is directed toward the equatorward (i.e., anticyclonic-shear) side of the streak, corresponding to higher geopotential height. There is also a significant along-jet component of the ageostrophic wind directed upstream, indicating that the actual wind in this

jet streak is sub-geostrophic (i.e., the actual wind speed in the core of the jet is smaller in magnitude than the geostrophic wind speed), a property that may be related to the cyclonically curved orientation of the jet streak. Nevertheless, this particular property is not generic; some jet streaks are approximately geostrophic in the along-jet direction, whereas others, particularly those that are anticyclonically curved, may be super-geostrophic. Explanations for employing the terminology of 'entrance' and 'exit' with regard to jet streaks and for the presence of sub-geostrophic and super-geostrophic along-jet flow will be provided subsequently.

Conceptual Models of Jet Streaks

Since the horizontal divergence is often a small residual between two larger kinematic quantities that are nearly equal in magnitude but opposite in sign, uncertainties arise in calculating the upper-tropospheric horizontal divergence directly from conventional upper-air data. These uncertainties may be particularly significant if the jet streak is located in a data-sparse region, or if the streak is so narrow that the observational network is unable to resolve accurately the structure of the streak. Consequently, the horizontal divergence has been inferred using air parcel arguments applied to the vector momentum equation and to the vorticity equation, the results of which have been portrayed schematically in terms of conceptual models relating horizontal divergence patterns to various aspects of the structure of jet streaks. Several well-known conceptual models of jet streaks are reviewed below: (i) models of straight and curved jet streaks; (ii) models of jet streaks coupled with other upper-tropospheric jet streaks or with lower-tropospheric frontal zones; and (iii) a model

Figure 3 ECMWF analysis on the 300 hPa pressure surface, valid at 1200 UTC 3 November 1995, depicting wind speed (values greater than 50 m s^{-1} shaded as indicated) and ageostrophic wind (arrows; vector scale indicated at bottom of diagram).

describing the life cycle of a jet streak embedded within an evolving synoptic-scale baroclinic wave.

Straight Jet Streaks

Perhaps the best known conceptual model of jet streaks, illustrated in [Figure 4](#), depicts a straight isotach maximum in which the isentropes are assumed to be oriented parallel to the jet axis. This conceptual model is often referred to as the ‘four-quadrant model’ because the upstream (entrance) and downstream (exit) regions of the streak are divided into left and right regions by the jet axis (with left and right defined facing downstream). To infer the nature of the ageostrophic flow and the horizontal divergence in this and subsequent conceptual models, it is convenient to adopt a natural coordinate representation of the frictionless vector momentum equation (eqns [1] and [2]).

$$v_{\text{agn}} = \frac{1}{f} \frac{DV}{Dt} \quad [1]$$

$$v_{\text{ags}} = -\frac{K_t V^2}{f} \quad [2]$$

Here v_{agn} and v_{ags} are the cross-stream and along-stream components of the ageostrophic wind in a ‘right-handed’ natural coordinate system such that $\mathbf{n} = \mathbf{k} \times \mathbf{s}$, $\mathbf{s} = \mathbf{V}/V$, V is the horizontal wind speed, and K_t is the parcel trajectory curvature. At the level of the jet core, the vertical velocity is assumed to be small and may be neglected; hence the Lagrangian rate of change $D/Dt (= \partial/\partial t + \mathbf{V} \cdot \nabla)$ may be defined following the horizontal flow.

In general, jet streaks travel at a speed that is slower than the maximum wind speed in the jet core. Consequently, air parcels travel through the streak, entering upstream and exiting

downstream – hence the terms entrance and exit regions introduced previously. An air parcel in the entrance region will experience increasing wind speed ($DV/Dt > 0$), and an air parcel in the exit region will experience decreasing wind speed ($DV/Dt < 0$). Since the curvature is negligible for the straight jet streak depicted in [Figure 4\(a\)](#), the along-stream component of the ageostrophic wind is small (see eqn [2]); the cross-stream component of the ageostrophic wind is directed from higher to lower values of geopotential height in the entrance region and from lower to higher values in the exit region (see eqn [1]). Away from the jet axis, where speed accelerations are weaker, the ageostrophic flow decreases in magnitude and thus there is convergence in the left entrance and right exit regions, and there is divergence in the right entrance and left exit regions. The vertical circulations transverse to the jet streak, depicted in [Figure 4\(b\)](#), are thermally direct in the entrance region and thermally indirect in the exit region. The sense of these circulations is consistent with the conversion from potential to kinetic energy required for an air parcel to increase its speed in the entrance region of the streak, and with the conversion from kinetic to potential energy required for an air parcel to decrease its speed in the exit region.

It is also possible to deduce the patterns of horizontal divergence illustrated in [Figure 4\(a\)](#) using the equation governing the evolution of the vertical component of the relative vorticity evaluated on an isobaric surface, ζ , again at the level of the jet core, given by eqn [3].

$$\nabla \cdot \mathbf{V} = -\frac{1}{(f + \zeta)} \frac{D\zeta}{Dt} \quad [3]$$

In addition to the neglect of the tilting, vertical advection, and friction terms, the Lagrangian rate of change of planetary vorticity is here assumed to be small in comparison to the rate

Figure 4 Schematic illustration, applicable to the Northern Hemisphere, of ageostrophic circulations and vorticity patterns for a straight jet streak. (a) Transverse ageostrophic wind components and associated patterns of convergence (CONV) and divergence (DIV) in the entrance and exit regions at the level of maximum wind. (b) Transverse ageostrophic circulations in entrance (cross-section A–A') and exit (cross-section B–B') regions of jet streak depicted in (a), along with schematic isentropes (dotted lines) and location of jet core (J). (c) Relative vorticity and associated advection patterns, with NVA and PVA indicating negative (anticyclonic) and positive (cyclonic) vorticity advection, respectively. From Uccellini LW and Kocin PJ (1987). The interaction of jet streak circulations during heavy snow events along the East Coast of the United States. *Weather and Forecasting* 2: 289–308. American Meteorological Society, Boston.

of change of relative vorticity. As illustrated in Figure 4(c), a straight jet streak exhibits cyclonic relative vorticity on its poleward side and anticyclonic relative vorticity on its equatorward side. Hence, an air parcel traveling downstream through the left entrance or right exit regions will experience an increase in cyclonic relative vorticity, and an air parcel traveling downstream through the right entrance or left exit regions will experience an increase in anticyclonic relative vorticity. Equation [3] indicates that convergence is expected in the left entrance and right exit regions, whereas divergence is expected in the right entrance and left exit regions.

The conceptual model shown in Figure 4 assumes that isentropes are parallel to the jet axis. For many observed jet streaks, however, this assumption is overly restrictive and the

isentropes are generally aligned at an angle to the jet axis. The effect of the resultant along-jet temperature advection on the patterns of horizontal divergence and vertical motion accompanying a straight jet streak is illustrated in Figure 5 for two different alignments of the isentropes relative to the jet axis. When there is cold advection along the jet (Figure 5(a)), the transverse vertical circulations are shifted toward the equatorward (anticyclonic-shear) side of the jet streak in the entrance region and to the poleward (cyclonic-shear) side in the exit region. Conversely, along-jet warm advection (Figure 5(b)) results in a shift of the transverse circulations to the poleward (cyclonic-shear) side in the entrance region and to the equatorward (anticyclonic-shear) side in the exit region. As depicted in these illustrations, these shifts in the vertical circulations can

Figure 5 Schematic illustration of geopotential height (heavy solid lines), wind speed (heavy dashed lines), and potential temperature (thin solid lines) associated with a straight jet streak for isentropes aligned at a small angle to jet axis: (a) along-jet cold advection; (b) along-jet warm advection. Arrows indicate the sense of the cross-front ageostrophic wind component, and the plus and minus signs indicate maxima and minima in the middle-tropospheric pressure-coordinate vertical velocity. Recall that positive (negative) values of this quantity correspond to downward (upward) motion. Adapted from Shapiro (1982).

lead to the maximum vertical motions being located beneath the jet axis, rather than to either side as in Figure 4. In the cold advection case, such a configuration may be important to the development of tropopause folds, which requires the presence of significant subsidence localized beneath the jet axis.

Curved Jet Streaks

Although evidence exists supporting the idealized structure of isolated straight jet streaks such as those depicted in Figure 4 and Figure 5, jet streaks exhibiting a four-quadrant pattern of horizontal divergence and vertical motion are the exception rather than the rule. The rarity of the four-quadrant pattern is a consequence of the fact that few jet streaks are immune to the effects of curvature: many jet streaks have curved axes, and even jet streaks that have straight axes tend to be embedded in a large-scale jet stream that may itself be curved. The influence of curvature on the horizontal divergence patterns associated with jet streaks may be considered by appealing to the schematic depiction of a steady curved jet stream shown in Figure 6, which exhibits uniform wind speed in the along-stream direction such that $DV/Dt \equiv 0$. Assuming that parcel trajectory curvature may be approximated by streamline curvature, eqn [2] implies that in the trough, where the curvature is cyclonic ($K_t > 0$ in the Northern Hemisphere), the ageostrophic wind is directed upstream ($v_{ags} < 0$) and the actual wind is

Figure 6 Schematic illustration of geopotential height (solid lines), wind speed (dashed lines; region of maximum wind speed shaded), ageostrophic wind (arrows) and associated patterns of convergence (CON) and divergence (DIV) in the vicinity of a curved jet stream exhibiting uniform wind speed in the along-stream direction. Adapted from Shapiro MA and Kennedy PJ (1981) Research aircraft measurements of jet stream geostrophic and ageostrophic winds. *Journal of the Atmospheric Sciences* 38: 2642–2652. American Meteorological Society, Boston.

sub-geostrophic, whereas in the ridge, where the curvature is anticyclonic ($K_t < 0$ in the Northern Hemisphere), the ageostrophic wind is directed downstream ($v_{ags} > 0$) and the actual wind is super-geostrophic. In the inflections between the trough and ridge, the along-stream ageostrophic wind is zero; hence, divergence is expected between the trough and ridge, whereas convergence is expected between the ridge and trough. Consequently, the pattern of horizontal divergence for a jet streak embedded in such a curved jet stream may be modified significantly from that shown in Figure 4(a), depending on where the streak is located with respect to the trough or the ridge. For example, for a jet streak located near the base of the trough, the convergence and divergence in the left entrance and left exit regions of the streak will be enhanced by the convergence upstream and the divergence downstream associated with the jet stream. As a result, the horizontal divergence may exhibit a two-cell pattern, rather than the four-cell pattern associated with a straight jet streak. The two-cell pattern appears to be more common, given the frequent association of jet streaks with so-called ‘short-wave troughs’ in the upper troposphere, which are characterized by cyclonic curvature.

Coupled Jet Streaks

Sometimes two separate jet streaks in the upper troposphere may come into such close proximity that the vertical circulations associated with these features become coupled. Such a configuration, depicted schematically in Figure 7, is common to cyclogenetic events that produce heavy snow along the East Coast of the United States. In this configuration, the left exit region of the equatorward jet streak and the right entrance region of the poleward jet streak become colocated, such that the divergence in the upper troposphere and the ascent below are enhanced. This coupling of the vertical circulations can lead to the organization of heavy precipitation and to the rapid development of the surface cyclone.

The vertical circulations associated with upper-tropospheric jet streaks can also interact with the corresponding circulations associated with lower-tropospheric jets and frontal zones.

Figure 7 Schematic illustration of surface cold and warm fronts, high and low pressure centers, sea level isobars (dotted lines), precipitation (shaded, with asterisks representing snow and dots representing rain), upper-level flow (arrows), upper-level trough axes (dot-dashed lines), and jet streaks (cross-hatched) associated with a 'typical' heavy snow event along the East Coast of the United States. From Uccellini LW and Kocin PJ (1987) *The interaction of jet streak circulations during heavy snow events along the East Coast of the United States*. *Weather and Forecasting* 2: 289–308. American Meteorological Society, Boston.

A hypothetical example depicting unfavorable and favorable configurations of upper-level and lower-level systems is provided in (Figure 8). In the unfavorable configuration (Figure 8(a,b)), the right exit region of an upper-tropospheric jet streak is located above a surface frontal zone. The subsidence associated with the jet streak in this region overlies the ascent associated with the surface frontal zone, acting to stabilize the air above the front and to suppress convection. In the favorable configuration (Figure 8(c,d)), the left exit region of the jet streak is located above the surface frontal zone, and the ascent associated with the jet streak can couple with the ascent accompanying the surface front, leading to the release of convective instability and to the outbreak of severe convective storms.

Jet Streak Life Cycles

The foregoing conceptual models treat jet streaks as static entities in the sense that their structure and amplitude remain steady, although they can translate or propagate. In reality, jet streaks undergo life cycles while interacting with the background-flow environment. A hypothetical jet streak life cycle is illustrated in Figure 9, in which the jet streak is traveling through and interacting with an evolving synoptic-scale baroclinic wave. In this scenario, the jet streak forms in the confluence zone situated within a trough-over-ridge pattern (Figure 9(a)). As the jet streak migrates into the north-westerly flow inflection between the

ridge and the trough (Figure 9(b)), the baroclinic wave amplifies. The jet streak subsequently advances toward the base of the trough (Figure 9(c)), at which time the wave is fully developed and after which time the wave decays as the streak travels through the south-westerly flow downstream of the trough (Figure 9(d)). Although this scenario is seldom observed in its entirety, it is common for an evolving jet streak to progress through at least one or several of the stages depicted in (Figure 9) during some portion of its life cycle.

Dynamics of Jet Streaks

The conceptual models of jet streaks presented above are based on hypothetical configurations of wind, geopotential height, and potential temperature fields, and on deductions based on air parcel arguments. However, it is not immediately obvious that these configurations correspond to realizable solutions, obtained using either analytical or numerical methods, to consistent sets of dynamical equations governing the evolution of the flow. To describe and understand the processes by which jet streaks evolve, it is desirable to refer to such solutions. In the balanced case, the dynamics of jet streaks may be described in terms of linear waves or nonlinear coherent vortices using the quasi-geostrophic system, whereas in the unbalanced case, the dynamics of jet streaks are strongly coupled to inertia-gravity waves.

Figure 8 Schematic illustration of vertically uncoupled (a,b) and vertically coupled (c,d) upper- and lower-tropospheric jet-front systems. (a) Upper-tropospheric jet exit region (isentachs, heavy solid lines; jet axis, solid arrow) aligned along and displaced toward cold side of surface frontal zone (isentachs, dashed lines; cold front marked conventionally) and lower-tropospheric jet (jet axis, open arrow). (c) As in (a) except for upper-tropospheric jet exit region aligned across surface frontal zone. (d) As in (b) except for cross-section along B-B' indicated in (c). Adapted from Shapiro (1982).

Jet Streaks and Baroclinic Waves

It was noted previously that jet streaks often play a significant role in extratropical cyclogenesis. In fact, there is evidence suggesting that jet streaks are an integral part of the upper-tropospheric baroclinic wave associated with cyclogenesis and of a dynamical process known as 'downstream development', which accounts for the growth and decay of many such waves. In the downstream development process, kinetic energy propagates from an upstream trough that is decaying toward a new trough that is growing downstream. This energy is maximized in the inflections between the troughs and ridges, and these kinetic energy maxima correspond to jet streaks. An idealized picture of the structure of a baroclinic wave undergoing downstream development is shown in [Figure 10](#). The evolution of the jet streaks in this process is consistent with the observation that many streaks appear to

'jump' between the north-westerly and south-westerly flow inflections of the wave, rather than translate continuously through the wave pattern, as is the case for the conceptual life cycle shown in [Figure 9](#).

Jet Streaks and Coherent Vortices

Observations suggest that, in some cases, jet streaks are associated with monopolar and dipolar vortices of mesoscale dimensions (length scales of approximately 500 km) that are embedded within a larger-scale jet stream. These features differ from the synoptic-scale baroclinic waves described above in that they do not disperse their energy; instead they travel coherently, maintaining their identities for periods of up to several weeks. A straight jet streak represented in terms of a symmetric vortex dipole solution to the quasi-geostrophic

The geopotential anomaly, ϕ' , relative to the time mean is positive/negative in the ridge/trough. Wave-relative air flow is indicated by heavy solid arrows and the ageostrophic wind is indicated by open arrows. Centers of maximum vertically integrated eddy kinetic energy are shown as ellipses. From Orlanski I and Sheldon JP (1995) Stages in the energetics of baroclinic systems. *Tellus 47A*: 605–628. Munksgaard International Publishers, Copenhagen.

system is depicted schematically in **Figure 11**; this schematic may be compared with its observationally based counterpart in **Figure 4**. In the representation depicted in **Figure 11**, the flow associated with the cyclonic vortex advects the anticyclonic vortex and vice versa, while the combined flow of both vortices results in a localized wind speed maximum (i.e., a jet streak) in the region between the vortices (**Figure 11(a)**). Hence the jet streak moves downstream in conjunction with the dipole, but at a slower speed than the maximum wind speed in the jet core, consistent with observations. The rotational component of the ageostrophic flow (**Figure 11(b)**), which dominates the total ageostrophic flow in the vortex dipole solution, exhibits a four-gyre circulation pattern consistent with the total ageostrophic flow pattern depicted in **Figure 3**. The divergent component of the ageostrophic flow (**Figure 11(c)**) is associated with a four-quadrant pattern of horizontal divergence consistent with that depicted in **Figure 4(a)**.

Unbalanced Flow in Jet Streaks

The foregoing discussion of the dynamics of jet streaks is predicated on the assumption that the flow satisfies some balance relationship connecting the wind and geopotential fields. In some cases, however, jet streaks do not satisfy any particular balance relationship; jet streaks are often characterized by Rossby numbers that are large compared with unity, and by large values of horizontal divergence and Lagrangian rates of change of this quantity. A well-documented example of an unbalanced flow configuration is that of an upper-tropospheric jet streak located in the south-westerly flow inflection between a trough and ridge in the circumstance where the distance between the trough and ridge is contracting. It has been hypothesized that this upper-tropospheric configuration is conducive to the generation of large-amplitude inertia-gravity waves in the lower troposphere, which may be accompanied by hazardous weather. Moreover, inertia-gravity waves associated with this configuration may be important in

Figure 11 Schematic illustration of a straight jet streak (region of maximum wind speed shaded) represented in terms of a quasi-geostrophic vortex dipole in a uniform zonal background flow. (a) Quasi-geostrophic potential vorticity, q , and geostrophic velocities associated with respective constituent vortices, such that solid arrows indicate flow induced by cyclonic vortex ($q > 0$, solid line) and dotted arrows indicate flow induced by anticyclonic vortex ($q < 0$, dotted line). Lake-Effect Storms

Synopsis

Lake-effect snow develops when sufficiently cold air passes over warm water. It is an integral part of the snowfall climatology for the Great Lakes Region of North America. The most intense snowfall situations occur when wind blows parallel to the long axis of a lake. Because the snow bands are only several kilometers wide but sometimes several hundred kilometers long, small changes in synoptic conditions can have big impacts on where the heaviest snow falls. Basic dynamics are well understood, but the specifics of which band type will form and where, are not. Forecasting lake-effect snow is still challenging. Lake-effect snow occurs in other parts of the world.

Introduction

Each winter, lake-effect storms develop on the downwind shores of the Great Lakes, as arctic winds blow across the relatively warm water. The associated clouds and snow (or rain) showers tend to organize in narrow bands, usually only a few kilometers wide but sometimes more than 200 km long. There may be one band, or there may be as many as 10 or 20, each separated by only a few kilometers of clear sky. These bands may remain stationary over a region or they may oscillate in a snakelike fashion. They may produce nothing more than 1 or 2 cm of snow, or they may dump more than 120 cm of snow in a single storm. These lake-effect storms are primarily a product of relatively simple cold air mass modification by warm water, complicated lakeshore geometry, and the prevailing synoptic situation.

Lake-effect storms develop in other parts of the United States, Canada, and the world, but nowhere else do they occur as frequently or with such intensity as they do in the Great Lakes region. The reasons for the unique weather in the Great Lakes region can be traced to several geographic aspects. The fact that the Great Lakes are the largest single source of fresh water in the world (except for the polar ice caps), the fact that the Great Lakes are situated approximately half way between the equator and pole, the fact that Great Lakes are located in the interior of a large continent, the fact that each of the lakes is approximately the size of a small inland sea, and the fact that there are several lakes – each separated by distances less than their own size, makes for some very unique weather in the region. Additionally, because of their depth, the lakes rarely freeze over completely, even in the coldest of winters, and thus remain a nearly continuous and very large source of heat and moisture for the atmosphere. Lake-effect storms continue to be a forecast challenge despite improvements in numerical weather prediction models because small changes in the prevailing synoptic conditions coupled with their meso- γ /meso- β scale size can lead to dramatic changes in snowfall totals for a given location.

Climatology

Lake-effect snow accounts for 25–50% of the total annual snowfall in many lakeshore regions (see [Figure 1](#)). The

snowbelts (areas of heavier snow) that shoulder the southern and eastern shores of the Great Lakes reflect the direction of the prevailing northwesterly flow relative to the orientation of the lakes, the sharp contrast in surface friction between the relatively smooth lake surface and the rough land, and terrain effects. The largest snowfall totals exist in the upper peninsula of Michigan, where northwesterly flow across Lake Superior is forced upward abruptly over steep terrain upon reaching the northern coast of the upper peninsula – especially around the Keweenaw Peninsula, and the Tug Hill Plateau in western New York, where west-southwesterly flow across the lower lakes provides a long fetch and ample opportunity for the air to be moistened and destabilized. In both of these locations, long fetches and orography are key aspects. Terrain can enhance individual snowstorm totals by about 5 cm for every 100 m of rise. Additionally, portions of the lakeshore with enhanced concavity promote convergence zones that can further enhance snowfall totals. Heavier lake-effect amounts typically fall during cold winters, when the lake-air temperature differences are enhanced.

Lake-effect snowfalls almost exclusively during the *unstable season* – that portion of the year when the lakes are climatologically warmer than the ambient air and thus provide heat and moisture to the lower atmosphere to destabilize it. Enhanced cloudiness and precipitation exist across much of the lakeshore regions and far inland as well. The percentage of cloudy days peaks in November for many places of the Great Lakes region – due in part to significant lake-enhanced cloudiness. Precipitation during the unstable season typically begins with episodes of nocturnal rain showers during cool nights in late August. As the mean air temperature drops through the fall months, lake-effect rain showers change to lake-effect snow showers. Much of the lake-effect snow typically falls between November and February, which constitutes the heart of the unstable season, when lake-air temperature differences tend to be greatest. Climatological lake-air temperature differences may be around 7–8 °C, but may exceed 30 °C during intense cold air outbreaks. Coupled with winds sometimes in excess of 20 m s⁻¹, combined surface sensible and latent heat fluxes can typically exceed 1000 W m⁻² – comparable to that found in a category 1 hurricane.

Lake-effect clouds and snow can occur locally on ~30–40% of the days in winter under a variety of synoptic

Figure 1 Average 1951–80 Great Lakes seasonal snowfall total. From Figure 2 in Norton, D.C., Bolsenga, S.J., 1993. patterns – whenever there is an onshore fetch and the lake-air temperature difference allows the lowest layers of the air to destabilize. However, certain synoptic patterns are more favorable than others for allowing lake-effect snow to develop. A typical sequence of events begins with a synoptic-scale low moving across the Great Lakes region from southwest to northeast (see [Figure 2](#)). Additionally, in late autumn especially, these lows are deepening as they cross the region because of baroclinic forcing and aggregate heating from all the lakes. Strong northwesterly winds on the back side of the low bring progressively colder polar or arctic air across the warm lakes. Subfreezing temperatures may reach as far south as the Gulf Coast and northern Florida, with -20°C readings just north of the lakes. The strong winds and cold air generate strong surface fluxes over the lakes that moisten and destabilize the air, leading to snow showers along the downwind lakeshores of the Great Lakes. The deepening of the low and the destabilization both allow stronger winds from above to mix down to the surface and further increase the heat and moisture fluxes.

Depending on the wind speed, the orientation of the wind flow relative to the long lake axis, stability, moisture, and upper-level forcing, different types of lake-effect storms can develop. Basically, when the prevailing flow is more parallel to the short axis than to the long axis of a lake (e.g., strong short-axis winds), multiple wind parallel bands (Type II) develop (see [Figure 3](#) middle panel). These bands are typically 2–4 km wide and spaced 5–8 km apart. Snowfall is usually spread over a large area of the downwind lakeshore and amounts are usually light (<4 mm liquid precipitation per day). When the prevailing short-axis winds are weak, midlake (Type I) or shore-parallel (Type IV) bands can

develop – even when the long-axis prevailing winds are strong (see [Figure 3](#) upper panel). These bands can be 10–20 km wide and generate copious amounts of snow. If the short-axis wind is essentially not present, then the band will be located near the middle of the lake. If the short-axis prevailing wind is present but weak, then the band will be located closer to the downwind shore. Sometimes, especially over Lakes Erie or Ontario, a midlake band will develop at an obtuse angle to the long axis of the lake. These bands (Type III) actually develop as midlake bands in northwesterly flow over Lake Huron, farther upwind (see [Figure 3](#) lower panel). They may lose their visible cloud characteristics over southern Ontario but maintain the convergence zone so they redevelop once they reach the lower lakes. If the wind is very light against areas of enhanced concavity, then lake vortices (Type V) may develop (see [Figure 3](#) upper panel). Stretching and tilting of vorticity from low-level convergence and vertical wind shear; differential diabatic heating; and synoptic-scale vorticity and temperature advection are thought to play roles in this type of lake-effect storm. [Figure 4](#) summarizes the relationship of storm morphology to lake-air temperature difference and wind speed.

The most common type of lake-effect event over the northern lakes (Superior, Huron, and Michigan) is the multiple band variety, which occurs 50% of the time. The next most common is the shore-parallel or midlake variety, which occurs 25% of the time. The remaining 25% includes meso-scale vortices, hybrid combinations, and undeterminable forms. The most common type of lake-effect event over the southern lakes (Erie and Ontario) is the shore-parallel or midlake variety, because of the different orientation of these lakes (see [Figure 5](#)). In general, the frequency of multiple

bands decreases from west to east and the frequency of shore-parallel and midlake bands increases from west to east across the region.

Boundary Layer Dynamics

When cold air flows across the warm waters of the Great Lakes, strong sensible and latent heat fluxes warm and moisten the air closest to the surface first, causing the lowest levels of the atmosphere to destabilize. Strong turbulent motions mix upward the warmed and moistened air in convective fashion. Steam fog typically develops and steam devils may be visible near the surface, especially within a few tens of kilometers of fetch. A very unstable convective internal boundary layer (CIBL) forms near the surface and grows rapidly upward in the downwind direction (see Figure 6). The upwind temperature, humidity, and flow characteristics of the air before it reaches the lake determine how the air will be modified. As the air crosses the downwind lakeshore, frictional convergence enhances ascent.

Convective updrafts can exceed $4\text{--}5\text{ m s}^{-1}$ in narrow, 100-m wide cores. After only a few kilometers of fetch, the depth of the internal boundary layer may reach or exceed the depth of

the planetary boundary layer. At some point, the air within the thermal internal boundary layer becomes moist enough and deep enough so that the lifting condensation level is below the top of the boundary layer and cloud forms (Type I boundary layer). Subsequent latent heat release and radiative heat transfer become important and increase the rate of entrainment. The clouds develop initially as two-dimensional bands but in time, with sufficient fetch and heating, these bands can develop into chains of three-dimensional cells and may eventually develop into a regular array of three-dimensional mesoscale cellular convection. Maximum cloud drop concentration and liquid water content (e.g., 0.25 g m^{-3}) occur near cloud-top and increase over the first two-thirds of fetch. Near the downwind lakeshore, snow particle production increases (e.g., 5 l^{-1}) to reduce drop concentration and increase the height of cloud base.

The most common type of convection associated with cold air outbreaks over the Great Lakes is longitudinal rolls. This type occurs in other parts of the world – wherever cold air crosses warm water. Over the Great Lakes, the rolls are usually oriented parallel to the wind at the base of the inversion and also to the low-level wind shear. Classical rolls are typically 2–5 km wide and 0.5–2 km deep so the aspect ratio is about

Figure 3 Lake-effect snow band structures. Upper panel shows a lake vortex (Type V) over Lake Huron (C); midlake band (Type I) over Lake Erie (A); shore-parallel band (Type IV) over Lake Ontario (B). Middle panel: multiple bands (Type II) over Lake Huron (A) and shore-parallel band (Type IV) over Lake Ontario (B). Lower panel: midlake band (Type I) over Lake Huron (A); hybrid band (Type III) over Lake Erie (B and C). Top panel from Figure 6 and middle and bottom panels from Figure 5 in Niziol, T.A., Snyder, W.R., Waldstreicher, J.S., 1995. Winter weather forecasting throughout the Eastern United States. 2–5. Rolls over the Great Lakes are 10–20 km wide and 1–2 km deep so the aspect ratio is about 10. Some roll circulations exhibit a multiscale configuration so that the cloud streets are best developed when the wavelengths of the convection and rolls are in phase. Such multiscale phasing can generate cloud streets with aspect ratios of 10–20. In many instances, other cloud structures are simultaneously present in addition to the longitudinal rolls (see Figure 7).

Linear analytic studies indicate that three different types of instability mechanisms may be responsible for rolls. First,

Figure 4 Diagram showing general conditions favorable for different lake-effect morphological regimes using wind speed vs lake-air temperature difference parameter space. The diagram is a composite based on the existing lake-effect literature. The dashed lines represent nondistinct boundaries between regimes. Idealized model simulations examining the mesoscale structure of winter lake-effect circulations. *Monthly Weather Review* 131, 206–221. Adapted with permission from the American Meteorological Society.

inflection point instability theory suggests that a dynamical instability can develop in a (rotating) Ekman layer that is neutrally stratified if the cross-geostrophic wind component exhibits an inflection point. The most unstable wind profiles lead to rolls with an aspect ratio of 3. Rolls are best developed when they are oriented about 14° to the left of the geostrophic wind (in neutral conditions). Second, parallel instability theory involves the curvature of wind speed profiles parallel to the roll axes and the boundary layer mean wind shear. This type of instability mechanism generates rolls with aspect ratios that are twice as large as those from inflection point instability and closer to those observed during lake-effect conditions. Third, convective instability (i.e., an unstable boundary layer) in the presence of wind shear also leads to the formation of rolls that are parallel to the mean wind shear but with aspect ratios that are smaller than those from inflection point instability (e.g., around 2).

Understanding roll development during lake-effect situations is further complicated by the fact that large-eddy numerical simulations suggest that only convective instability is capable of generating rolls. Gravity waves generated within the stable air above the convective boundary layer by wind shear near the boundary layer top have also been suggested as a possible mechanism. If the wind shear at the top of the boundary layer is roughly perpendicular to the boundary layer wind direction, then bands of convection that are parallel to the mean boundary layer wind can be induced by gravity waves. Latent heat release, cloud-microphysical processes, and low-level wind shear (e.g., below 200 m) may also influence the development of rolls. The partial agreement between observations and theoretical studies thus far suggests that a combination of mechanisms may be responsible for different aspects of roll development or during certain conditions.

Sensitivity to Synoptic Conditions

The thermal modification of air over relatively cold land as it crosses a relatively warm lake results in a horizontal temperature gradient across the lakeshore, which can generate a thermally direct solenoidal circulation similar to that of a sea/land breeze. In that sense, it can be seen that the lake-air temperature difference, speed and direction of the prevailing wind, and height and strength of the capping inversion are perhaps the most crucial parameters for determining not only how much lake-effect snow will fall but also how it will fall. For example, for conditions characterized by moderate lake-air temperature differences ($>10^\circ\text{C}$) and strong winds ($>10 \text{ m s}^{-1}$) blowing across the short axis of a lake, multiple snow bands will usually develop. If the winds across the short axis are lighter and/or the temperature difference is greater, then some form of shore-parallel band will develop. If the wind is very light against

areas of enhanced concavity, then lake vortices can develop (see Figure 4).

The impact of the wind speed on the lake-effect response characteristics can be analyzed two-dimensionally in terms of the Froude Number $Fr = \pi U/NH$, where U is the mean wind speed across the short axis of the lake, and N and H are the Brunt–Väisälä frequency and depth of the planetary boundary layer respectively. The values for N and H depend on the lake-air temperature difference and stability of the prelake-modified air. The Froude number may be interpreted as the ratio of the mean wind speed U to the gravity wave speed $c_g = NH/\pi$ for a boundary layer of depth H . Three regimes are important to consider. When $Fr < 1$, the gravity wave speed exceeds the mean flow speed ($c_g > U$). Opposing sea-breeze type circulations develop with respect to the short axis of the lake and the heaviest precipitation falls over the lake (see upper panel in Figure 8). This regime corresponds to the midlake band

Figure 7 Superrapid scan Geostationary Operational Environmental Satellite (GOES) visible imagery (1-km resolution) for 1743 UTC on 10 Jan 1998. (a) Visible image over Lake Michigan region; (b) analysis of cloud structures in image. Major categories of cloud structures are labeled as type A–C bands with their approximate spacing and orientation relative to winds at the inversion level. From Figure in Tripoli, G.J., 2005. Numerical study of the 10 January 1998 lake-effect bands observed during lake-ICE. *Journal of Atmospheric Sciences* 62, 3232–3249. Adapted with permission from the American Meteorological Society.

type of event. When $Fr > 1$, the gravity wave speed is less than the mean flow speed ($c_g < U$). The response is characterized by alternating regions of ascent and descent that propagate downwind from the leeward shore, and precipitation is diffuse and weak. This regime corresponds to the multiple band type of event (see middle panel in Figure 8). When $Fr = 1$, the gravity wave speed equals the mean flow speed ($c_g = U$). A resonance condition develops where gravity waves that are generated at the downwind shore cannot propagate upwind. This regime corresponds to the shore-parallel band type of event that can generate significant precipitation at the downwind lakeshore (see lower panel in Figure 8). Setting $Fr = 1$, and using typical values of $N = 10^{-2} \text{ s}^{-1}$ and $H = 2 \text{ km}$, suggests that a value of $U \sim 6 \text{ m s}^{-1}$ maximizes heavy snow along the downwind lakeshore, which is consistent with observations.

The impact of fetch on lake-effect storm development has been known since the early 1900s. Long fetches usually result in heavy snowfalls. Short fetches also may produce significant

Figure 8 Gravity wave interpretation of lake-effect morphology dependence on wind speed. (a) Weak wind speeds create subcritical ($Fr < 1$) regime, which allows gravity waves to propagate upwind and downwind and a midlake band and moderate snow to develop over the lake; (b) strong wind speeds create supercritical ($Fr > 1$) regime, which allows gravity waves to propagate only downwind and multiple bands and light snow to develop beyond the downwind lakeshore; (c) moderate wind speeds create near-critical ($Fr \sim 1$) regime, which allows gravity waves to travel downwind but traps gravity waves trying to propagate upwind – resulting in an intense shore-parallel band and heavy snow to develop along the downwind lakeshore. Heavy arrows indicate wind speed and wavy arrows indicate gravity wave propagation. Plus (+) signs and shaded columns indicate ascent; minus (−) signs and open ovals indicate descent. Asterisks indicate snowfall.

snowfalls if the prelake-modified air is relatively unstable, if the lakeshore geometry enhances radial convergence, or if the nearby orography enhances lifting. These observed impacts of fetch have only been recently confirmed using analytic and numerical models. For example, it has been shown analytically for Lake Michigan that three convergence centers develop near the eastern shore when a westerly wind prevails, two cells or snow bands develop when a northwesterly wind prevails, and one midlake band develops when a northerly wind prevails. In some instances, the Rossby Number Ro , another nondimensional parameter, defined as U/fL , where f is the Coriolis parameter and L is the characteristic length scale of the lake (fetch), is useful for understanding lake-effect storm morphology. Ro can be thought of as the ratio of the time for Earth's rotation to become effective to the advective time it takes for an air parcel to cross the lake. Low values correspond

to a vortex structure, medium values correspond to a shoreline band, and high values yield multiple bands.

The vertical structure of the environmental wind also affects lake-effect storms. For example, when the prevailing wind is parallel to the long axis of Lake Erie, moderate directional shear (e.g., between 30 and 60°) from the surface to 700 hPa causes weakly to moderately precipitating multiple snow bands rather than a single intensely precipitating snow band to occur. Stronger shear (e.g., greater than 60°) over Lake Erie causes the breakdown of precipitating snow bands altogether – allowing only instead the development of a nonprecipitating stratocumulus deck. While wind shear can understandably inhibit the organization of rolls or wider bands, it is not clear whether some of the observed effects from shear are simply a manifestation of a shallow boundary layer.

The height and strength of the (capping) inversion are significant limiting factors to cloud depth and therefore to precipitation. Typically, the boundary layer must have a depth greater than 1 km in order for lake-effect snow to develop. The most convectively active lake-effect storms have inversion heights exceeding 3 km. Sometimes the capping inversion is entirely absent. During such cases, thunder and lightning typically accompany copious (e.g., exceeding 10 cm h^{-1}) snowfall rates.

The vertical temperature and moisture distributions within the boundary layer also play a role. For example, it has long been known that a minimum temperature difference of 13°C between the lake surface and the upstream airflow at 850 hPa is required for lake-effect storms to develop. This temperature difference criteria means that the lapse rate should be unstable with respect to unsaturated ascent. A dry boundary layer is less conducive for lake-effect snow than a moist one, although a long fetch can compensate for very dry boundary layers. The impact of moisture is greater for low-stability profiles than for high-stability ones.

The presence of large-scale forcing can also influence lake-effect storm development. Typically, the coldest air passes over the lakes as high pressure at the surface moves eastward across them, accompanied by negative vorticity advection at upper levels and cold advection near the surface. Thus, the impacts of synoptic-scale forcing typically act to suppress lake-effect storm development (see Figure 2). There are however instances when cold air, positive vorticity advection and even warm advection exist simultaneously over the region. Such situations usually come in the form of Alberta Clippers (short waves) that develop in cold air masses and move southeastward across the region. The synoptic forcing coupled with the cold air that is already established over the region can combine to generate intense snowfall.

Sensible and latent heating from all the Great Lakes (e.g., the lake aggregate) can also influence lake-effect storms over individual lakes. Basically, if warming (and moistening) occurs over all the Great Lakes for at least a day, then surface pressures and stability can drop over a broad region and cause a perturbation aggregate-scale, low-level cyclonic circulation to develop. The position, the size, and the warmth and moisture from this aggregate circulation can modify lake-effect precipitation throughout the region. Specifically, when the synoptic-scale flow is northwesterly, aggregate effects can augment snowfall along the northwestern shores of lower Michigan, and reduce snowfall along the southwestern shores (cf Figure 9).

Figure 9 Illustration of lake-aggregate effect on prevailing winds and lake-effect snowstorms. On the south side of the developing warm plume (shaded oval), northwest winds respond in sea-breeze fashion to become southwest winds with increased fetch and heavy snow across Lake Erie. Lake-effect snows across portions of western Michigan (lower peninsula) may or may not change characteristics. On the north side, northwest winds respond to become north-northwesterly winds with reduced fetch and light snow across Lakes Superior and Ontario and increased fetch heavy snow across Lake Huron. Heavy and light snow bands indicated by solid gray-shaded scalloped and gray-striped cloud strips, respectively.

Shore-parallel bands located offshore can migrate eastward (e.g., onshore) or evolve into multiple bands. These aggregate affects over Lake Michigan include enhanced westerly flow, increased heat and moisture, and lower stability. The lake aggregate can also influence lake-effect precipitation in the lower lakes region. For example, as the lake-aggregate-induced plume of heat and moisture extends southeastward, surface winds across Lake Ontario (north of the aggregate-induced plume) can become more northerly. In contrast, surface winds across Lake Erie (south of the aggregate-induced plume) can become more westerly. The aggregate-altered winds can cause a longer fetch across Lake Erie and a shorter fetch across Lake Ontario, and can shift the regions of lake-effect convective bands, so that less and less-intense lake-effect precipitation can fall along the lakeshores downwind (east) of Lake Ontario and more lake-effect precipitation can fall along the eastern shores of Lake Erie (cf Figure 9).

Forecasting

The mesoscale nature of lake-effect storms, their intensity, and the short development times continue to challenge forecasters. Highly variable snow-to-liquid ratios ($10:1$ – $50:1$) and terrain effects, especially near Lakes Erie and Ontario, can enhance the inherently large spatial variability of lake-effect snow and hence the forecast challenge. While the problems of forecasting when lake-effect snow is going to occur have essentially been solved, the equally significant problems of exactly where lake-effect

snow will occur, what form(s) it will take, how intense it will be, and how long it will last remain outstanding forecast issues. A combination of high-resolution numerical weather prediction models, statistical methods, Doppler Radar, and forecaster savvy are the basic forecast tools.

Numerical models have come a long way since the use of the Limited Fine Mesh (LFM) model. The coarse resolution (180 km) and the exclusion of the lakes in terms of their heat, moisture, and momentum characteristics in that model precluded any explicit model development of lake-effect precipitation. Regardless, operational forecasters relied on this model because of its ability to forecast the large-scale conditions, to which lake-effect snowstorm development is very sensitive. The LFM, in conjunction with forecaster decision trees based on key large-scale parameters, and experience, allowed forecasters to at least be able to issue general forecasts of when lake-effect snow was going to occur. Two operational models currently being used include the North American Model with 4 km resolution over the continental United States that runs four times daily out to 84 h, and the Rapid Refresh Weather Research and Forecast (WRF) Model with 13 km resolution that runs hourly out to 18 h.

Despite significant improvements in numerical weather prediction and the high-resolution model output provided by the National Centers for Environmental Prediction (NCEP), lake-effect snow continues to challenge the abilities of even

the most sophisticated numerical forecast models because of several inadequacies. These inadequacies include horizontal resolution that is still too coarse for resolving the 2–4 km wide bands, convective schemes tuned originally for deep (tropical) convection that are inappropriate to simulate intense shallow precipitating convection, and boundary layer schemes that are too simplistic to develop the low-level temperature, moisture, and cloud-microphysical structures that exist within lake-effect snow environments near the surface.

To supplement the NCEP information, forecasters at several National Weather Service Forecast Offices (WSFOs) in the Great Lakes region run their own versions of WRF, based on the WRF Environmental Modeling System. These regionally run versions include better-defined Lake Surface Temperatures and ice presence through NASA-SPoRT, and the ability for local forecasters to run simulations at very high (1 km) resolution and to generate ensembles that provide probabilities for different forecast scenarios. Additionally, forecasters still use various statistical methods. These methods were used almost exclusively prior to the existence of numerical models. As early as the middle of last century, various investigators had outlined conditions necessary for prolonged lake-effect storms to occur at the eastern end of Lake Erie (cf Figure 10). Highly sophisticated statistical methods, such as BUFKIT, are still used today in conjunction with numerical forecast model output to optimize the accuracy of lake-effect snow forecasts.

Polar Lows

Synopsis

Polar lows are subsynoptic-scale cyclones that develop poleward of the main polar front over the ocean. Polar lows are the most intense variety of a general classification of polar mesoscale cyclones. They are typically less than 1000 km in scale and last for just 12–48 h, although they can have associated surface wind speeds of over 30 m s^{-1} (60 knots). Their scale and brief life cycle make them difficult to observe and forecast, therefore a genuine maritime hazard. Their role in the climate system and their outlook in a changing climate are topics of current research.

Introduction

Through the years, mariners of the Nordic Seas have told tales of unexpected encounters with fierce storms that appeared out of nowhere to wreak havoc on the seas. These storms were smaller and more transient than the more predictable synoptic-scale weather systems that they were used to; yet with the advent of the satellite era, it appeared these smaller scale vortices were ubiquitous over the polar seas. The high latitude location of these storms, and their identification as low pressure centers, led to them becoming known as polar lows; although a host of alternative names have been used in reference to such weather systems, for example, Arctic instability lows, comma clouds, and, in the Southern Hemisphere, Antarctic coastal vortices. Polar lows are now defined as intense maritime cyclones with scales less than 1000 km and near-surface wind

speeds in excess of 15 m s^{-1} . Polar lows are the most intense example of the family of mesoscale cyclonic vortices, poleward of the main polar front, known generically as polar mesoscale cyclones. This article will discuss both, but will focus on those more energetic systems known as polar lows.

Polar lows are characterized as subsynoptic in scale, typically, 100–500 km in diameter, and short lived, lasting only 6–48 h. They develop over water, but often move over land or ice where they tend to fade rapidly. In terms of dynamics, polar lows are fundamentally baroclinic or convective in nature. In most cases, some element of convection is necessary for rapid development to an intense polar low. Purely baroclinic, or topographically forced, systems tend to remain as weaker polar mesoscale cyclones. One of the most prominent hallmarks of a polar low is the spiral of cloud associated with the vortical flow (**Figure 1**).

Figure 1 Infrared satellite image of the Barents Sea area at 02:40 UTC 13 December 1982. Light colors represent cold brightness temperatures. A polar low is well defined by a cloud vortex with a clear central eye. Image courtesy of the NERC Satellite Receiving Station, University of Dundee.

Occasionally, there is a clear eye at the center of the cloud vortex suggesting an analogy with tropical cyclones, indeed such systems have been described as Arctic hurricanes. More often than not they are warm-cored vortices, and many have well-defined fronts, suggesting parallels with synoptic-scale extratropical cyclones.

The distribution around the globe of the landmasses, sea ice, and sea surface temperatures leads to some favored locations for the development of intense polar lows. These are regions prone to cold-air outbreaks, where relatively cold continental air is advected over relatively warm ice-free waters. For example, in the Nordic Seas (the Greenland, Iceland, Norwegian, and Barents seas), the Irminger Sea, the Labrador Sea, the Bering Sea, the Gulf of Alaska, and the Sea of Japan. In the Southern Hemisphere, the eastern Weddell, the Bellingshausen, and the Ross seas are favored locations. Satellite- and model-based climatological studies show there are typically hundreds of polar mesoscale cyclones per year in each of these regions, with perhaps 10–20% being more intense polar lows. In the Northern Hemisphere, polar mesoscale cyclone development is most common during winter, followed by the autumn and spring seasons. In the Southern Hemisphere, there appears to be no significant seasonal variability, but there are preferences in location that tend to be dictated by variations in the sea ice distribution.

Polar lows are extremely important weather systems for certain regions as their strong winds and severe weather are potentially hazardous. However, it is also likely that polar mesoscale cyclones play an important, but as yet unclear role in the climate system at high latitudes; for example, through a strong coupling of the polar atmosphere and ocean through air–sea heat exchange. It has been suggested that the distribution of polar lows will move poleward under current climate

change projections, leading to fewer impacting Norway for example.

Observations of Polar Low Structure

Polar mesoscale cyclones are relatively small scale and short lived, which make them difficult to observe by conventional means as they tend to fall between the spatial and temporal gaps in the observing network. Their location in sparsely populated or maritime regions compound this difficulty. With the advent of the satellite era, and the development of satellite remote sensing as a tool for meteorological observation, our knowledge has vastly improved; not least in simply providing visible and infrared images showing the cloud structures associated with the systems (e.g., [Figures 1 and 2](#)).

Instrumented Aircraft Data

The availability of satellite imagery in real time has allowed the targeting of incipient polar lows for further investigation by instrumented aircraft. Only a very small number of polar lows have been investigated by aircraft, but these few cases provide otherwise unobtainable details of their structure. One case from over the Norwegian Sea in February 1984 is discussed as an illustration. [Figure 3](#) shows an infrared satellite image: light colors represent colder brightness temperatures and therefore generally higher clouds. There is a high comma-shaped cloud spiraling into the center of a mature polar low and contrasting with the warmer brightness temperatures of the sea surface beneath. To the south and east there are plumes of cloud associated with shallow convection. Further

to the south is an elongated band of high cloud associated with a synoptic-scale weather system.

An instrumented aircraft made a number of passes through the polar low over a period of a few hours centered at this time. Atmospheric soundings from dropsonde releases and nearby radiosonde ascents, along with the flight-level data, have been synthesized together to produce a highly detailed picture of this particular polar low. A surface pressure analysis, along with part of the aircraft track and wind observations at 300 m above sea level, is shown in [Figure 4](#). Note the analysis has been time-adjusted for the motion of the low during the aircraft sampling. The low was about 400 km across with 12 mb of closed isobars. The lowest sea-level pressure recorded was 979 mb at the point of calm winds. The low was not axisymmetric, rather somewhat elongated on a northeast–southwest axis. Mesoscale fronts in these directions (dashed lines) mark a strong horizontal wind shear, where the flight-level wind barbs show abrupt changes in direction over tens of kilometers. Wind speeds were over 30 m s^{-1} in the western and southern parts of the low. The relative vorticity of the flight-level winds was an S-shape, following the mesoscale fronts, with typical values over $10 \times 10^{-4} \text{ s}^{-1}$ and peak values of twice that. The relative vorticity values were on a par with those observed in synoptic-scale extratropical cyclones. The 300-m temperature field showed a secluded warm core, 2–3 °C warmer than surrounding temperatures, and of a similar elongated shape to the pressure field. The low was relatively shallow with only a weak circulation signature in the midtroposphere.

The low's vertical structure is illustrated in a cross section of potential temperature contours and storm-relative transverse velocity vectors in [Figure 5](#). The cross section is oriented approximately north–south at about 4° W. To the north (left) was a 1-km deep near-neutral marine boundary layer capped by a stable layer (bold lines). To the south (right) the marine

boundary layer was about 2-km deep. In the center of the cross section was a warm front, delineated by a strong horizontal gradient in potential temperature. There was low-level (storm-relative) convergence into the frontal region and vigorous ascent – the upward vertical velocities reaching 1 m s^{-1} . There was weaker descent on the warmer side of the front, completing a cross-frontal circulation. The warm-core structure of the system is depicted by the downwelling potential temperature contours above the frontal region. Cross sections of equivalent potential temperature showed a decrease in height up to about 2 km in the convergence region: in other words, the frontal region was unstable to moist convection. Convective precipitation was observed in this region, as radar reflectivity echoes, in a shallow layer below 3 km. Surface turbulent heat fluxes were calculated to be extremely high, up to 500 W m^{-2} for both surface sensible and latent heat fluxes. The total surface turbulent heat fluxes in this case were on a par with those observed in tropical cyclones (hurricanes). In some respects, for example, the fronts and the pressure distribution, this polar low was similar to archetypal synoptic-scale extratropical cyclones (see *Synoptic Meteorology: Extratropical Cyclones*). However, the large surface turbulent heat fluxes and clear eye ([Figure 3](#)) are reminiscent of tropical cyclones (see *Tropical Cyclones and Hurricanes: Hurricanes: Observation*).

The observations summarized above paint a vivid picture of a small-scale vortex, with remarkably strong winds, well-defined mesoscale fronts, and a number of convectively unstable areas where precipitation was falling. This structure is typical of many intense baroclinic-convective types of polar low. However, other case studies have shown more axisymmetric systems, with less well-defined fronts than illustrated above (e.g., [Figure 1](#)); or systems without areas of conditional instability, where convection is less important; or systems where upper-level forcing is vital. Clearly there is

Figure 4 A surface pressure analysis for 13:40 27 February 1984. Overlaid is the track of the instrumented aircraft and the observed flight-level winds. Each full-tick on the wind barbs is 5 m s^{-1} . S-shaped mesoscale fronts curving to the northeast and the southwest are depicted as dashed lines. a spectrum of characteristics within the polar low category of systems. Of course this amount of structural detail is not routinely available, instead in recent years we have come to rely on satellite remote sensing for much information.

Satellite Remote Sensing Data

The most vivid satellite observations of polar lows, and polar mesoscale cyclones, are the high-resolution infrared and visible images such as those in Figures 1–3. These images are simply pictures taken from space at certain wavelengths in the infrared or visible parts of the spectrum. The highest resolution (250–1000 m) images are from sensors on board polar orbiting satellites, for example, the Advanced Very High Resolution Radiometer (AVHRR) or the Moderate Resolution Imaging Spectroradiometer. These provide a fantastically detailed picture of cloud structure and height, often hinting at streamlines through the shape of the clouds. Also flown on many polar orbiting satellites are vertical sounders, which combine a variety of infrared and microwave channels to obtain atmospheric emission temperatures from several heights and thus temperature or humidity profiles for an atmospheric column. Such data have been used to obtain the synoptic backdrop to polar low development and, for example, to corroborate the warm-cored nature of the polar low described above. One limitation of these sounders is their poor functionality in areas of very thick clouds, where the humidity retrievals in particular are affected. This problem is largely bypassed when a more comprehensive passive microwave sounder is used, such as the

Special Sensor Microwave/Imager (SSM/I). This instrument can provide contemporaneous fields of precipitation, cloud liquid water content, and surface wind speed, at a resolution of around 100 km, although again heavy rain can interfere with the sensors. Observations from the SSM/I have helped to determine whether some mesoscale vortices are convective, or not, as convective precipitation gives a strong backscatter at certain wavelengths. Surface wind speed can also be measured by radar altimeters (such as Geosat), again through the influence of the winds on the sea state, and thus the radar backscatter. But due to their narrow swaths these sensors only provide cross sections through weather systems. To obtain both wind speed and wind direction from space, one has to revert to scatterometers (such as QuikScat or ASCAT): these are able to measure capillary waves on the ocean's surface and so infer wind speed and wind direction. They have a resolution of typically 25 km, but a relatively narrow swath or gaps within the swath. In addition, there is an ambiguity problem in determining the wind direction. To rectify this, external information such as wind data from numerical weather prediction models must be supplied. Surface wind data from scatterometers are at a suitable resolution for polar mesoscale cyclone investigations and have assisted in a number of case studies and climatologies. It has been shown that around 75% of cloud vortices (seen in AVHRR imagery) have a distinct surface circulation signature in scatterometer winds.

A large amount of operational satellite remote sensing data are now incorporated, via the data assimilation processes, directly into operational numerical weather prediction models and are thus implicit in meteorological analyses or reanalyses products. This includes vertical sounder temperatures, pressures, or thicknesses (etc.), passive microwave radiances, cloud-track winds, and scatterometer winds. Depending on the resolution and quality of the data assimilation and modeling system, this has resulted in many more polar mesoscale cyclones being represented in numerical weather prediction analyses, reanalyses, and forecasts.

Dynamical Theories of Polar Low Development

A number of dynamical mechanisms have been proposed for the initiation and growth of polar lows and polar mesoscale cyclones. The two most widely accepted theories being that polar lows are fundamentally baroclinic disturbances or fundamentally convective disturbances. A wealth of observational and numerical modeling studies would now suggest there is a continuous spectrum of polar mesoscale cyclones that spans these, and other, development mechanisms.

Baroclinic Dynamics

The classic baroclinic instability mechanism, as first developed in the 1940s and the 1950s, plays a primary role in the development of synoptic-scale extratropical cyclones (see **Dynamical Meteorology: Baroclinic Instability**; **Synoptic Meteorology: Extratropical Cyclones**). Essentially a continuously stratified fluid is unstable to small amplitude perturbations, if the basic state encompasses a reversal in sign of the potential vorticity (PV) gradient. The simplest archetype of

baroclinic instability is that of a zonally symmetric atmosphere, with a rigid lid of height H , a meridional potential temperature gradient Δ (equivalent to a zonal vertical shear – assuming thermal wind balance), a Coriolis force f , and a static stability N . Here the PV gradient reversal is at the boundaries. The growth rate is a linear function of $f\Delta/N$, and the scale of the unstable waves is a linear function of NH/f . For typical midlatitude values this yields e-folding times of about a day and fastest growing modes on the scale of several thousand kilometers. This is an order of magnitude larger than that of observed polar mesoscale cyclones; so to use this theory to explain mesoscale cyclones, it requires a scale reduction through a modification of the basic-state atmosphere. For a start, at high latitudes f is larger, but more importantly both H and N can be much smaller than is typical at midlatitudes. For example, during cold-air outbreaks the atmosphere can be represented as a near-neutral marine boundary layer capped by a strongly stable free atmosphere (e.g., **Figure 5**). In this case, if the rigid lid is taken as the strongly stable capping layer this means a much reduced H , and a reduced N in the near-neutral layer, leading to fastest growing modes on about the scale of observed polar lows (**Figures 3 and 4**). A different basic state, also leading to a scale reduction, is that of a reverse shear flow; so called because the baroclinic waves propagate in the opposite direction to the thermal wind, i.e., the shallow extent of the waves means their steering level is within the reverse flow. Here weak static stabilities and strong vertical shears can combine to yield unstable modes of the order 500 km.

A different paradigm of baroclinic instability is the initial value problem: where an upper-level precursor, such as an upper-level PV anomaly, induces growth at low levels. This scenario can also be envisaged through cyclonic vorticity advection and omega equation arguments, but is perhaps more transparent within an isentropic PV framework (see **Dynamical Meteorology: Potential Vorticity**). To achieve rapid growth, an upper-level PV anomaly must act in synergy with a low-level baroclinic zone, i.e., a potential temperature gradient (see **Figure 6**). The induced circulation from the upper-level PV anomaly deforms the low-level temperature field into a wave, which then induces its own cyclonic circulation, as potential temperature anomalies at a boundary are equivalent to PV anomalies. The upper- and lower-level anomalies reinforce each other's circulation and thus mutual growth occurs. In this scenario, the scale of the disturbance is again a function of NH/f . The presence of an upper-level PV anomaly is often associated with the intrusion of the stratosphere down into the troposphere, i.e., a low dynamical tropopause. In this case, the scale height H is reduced and (as before) when this is combined with low static stabilities, growth on the scale of polar lows is induced. This type of PV thinking has helped to explain a number of observed and modeled polar lows. It has also enabled another form of satellite remotely sensed data to be used, as stratospheric intrusions (i.e., PV anomalies) can be detected from their large total column ozone amounts.

Baroclinic instability mechanisms are significantly modified by the presence of moisture: latent heat is released through condensation of water vapor during ascent, and this additional heating reinforces the baroclinicity of the system and thus enhances growth. The most intense polar mesoscale cyclones

Figure 6 The interaction of an upper-level potential vorticity (PV) anomaly (+ sign) with a low-level baroclinic zone. The cyclonic circulation induced by the upper-level PV anomaly is illustrated through the solid curves. Panel (a) shows the initial state. Panel (b) shows the advection of the low-level potential temperature field into a warm anomaly. At the surface this is equivalent to a positive low-level PV anomaly (open + sign) and thus induces a cyclonic circulation illustrated through the open curves. The interaction is self-reinforcing and leads to rapid cyclogenesis. Adapted from Hoskins, B.J., McIntyre, M.E., Robertson, A.W., 1985. On the use and significance of isentropic potential vorticity maps. *Quarterly Journal of the Royal Meteorological Society* 111, 877–946 with permission.

tend to form as polar lows in maritime environments, where there is a ready supply of moisture, which suggests that any baroclinic dynamics are likely to be enhanced by latent heating. Indeed a number of numerical modeling case studies have found that without moist processes the modeled polar low is unable to grow to the strength observed.

Convective Dynamics

The axisymmetric cloud and the presence of a clear central eye in some polar lows (e.g., [Figure 1](#)) have suggested that these lows may be akin to small tropical cyclones. This idea has been pursued through the modification of some tropical cyclone development theories to polar environments. One such mechanism is conditional instability of the second kind (CISK – see **Dynamical Meteorology: Wave-CISK**). This mechanism involves the organization of cumulonimbus convection into a coherent weather system. An initial disturbance causes low-level convergence and ascent, which, in a conditionally unstable atmosphere, gives rise to latent heat release. This generates cyclonic relative vorticity that forces further low-level convergence and, by continuity, high-level divergence. The low-level convergence provides a continued source of moisture for further latent heat release and thus a positive feedback is established. The scale of CISK-driven disturbances is determined by the vertical distribution of diabatic heating during development. The growth rate is directly dependent upon the convective available potential energy (CAPE) of the atmosphere. In the polar regions, during cold-air outbreaks, extremely deep conditionally unstable layers can develop, thus providing enough CAPE for polar low development. However, it has also been argued, and observed from soundings, that the atmosphere does not sustain the required amounts of CAPE for long enough to allow the CISK mechanism to act as described.

An alternative convective theory is that of wind-induced surface heat exchange (WISHE) – also known as air–sea interaction instability – see **Tropical Cyclones and Hurricanes: Hurricanes: Observation**. This proposes that surface sensible and latent heat fluxes are responsible for the growth of tropical cyclones and polar lows. Moist convection mixes this additional heat and moisture through the troposphere on the scale of the growing vortex. Latent heat release within the convective

clouds contributes to vortex growth, and as the surface turbulent heat fluxes are proportional to the surface winds, a positive feedback is established. The theory allows an estimate of the central pressure drop within a mature system from Carnot energy-cycle arguments and known environmental conditions; for example, the observed pressure drop of the polar low in [Figure 1](#) is consistent with this theory.

In some sense the above two mechanisms are variations of convective closure rather than being fundamentally different. CISK relies on low-level convergence from friction, where WISHE does not, but on the other hand, it could be argued that CISK implicitly includes surface sensible and latent heat fluxes as part of the dynamics. Recent idealized numerical modeling studies have found that polar low growth is more sensitive to the parameterization of surface heat fluxes than to the parameterization of surface friction, which provides some evidence for the WISHE mechanism, but in the real world the two mechanisms are more difficult to distinguish. A common requirement for the convective theories is an initial disturbance of the basic state about which the convection can become organized. This begs the question, what causes the initial disturbance? In many observational and numerical studies, it would appear that some sort of baroclinic forcing causes the initial disturbance. As described in the previous section, this may be a linear instability of a baroclinic atmosphere or an upper-level precursor inducing flow at low levels. The initial polar low can then evolve into a convectively driven phenomenon, if the conditions are right. In other cases perhaps a topographic forcing, or a barotropic forcing, causes the initial disturbance. What is clear, is that moist convection plays a central role in the development of many polar lows in a way that it does not in other extratropical cyclones.

It has been found that long-wave radiative cooling generally increases the growth rate and maximum intensity of polar lows, due to enhanced cooling of the cyclones environment relative to its warm core.

Numerical Modeling and Forecasting of Polar Lows

In a research context, numerous case studies have shown that state-of-the-art numerical models are able to simulate polar

lows, and polar mesoscale cyclones, of all varieties. In fact, numerical modeling studies have been instrumental in elucidating the different roles of the dynamical mechanisms discussed above. To capture the growth and mesoscale structure to a reasonable accuracy, it typically requires the parameterization of microphysical processes (including latent heat release, cloud microphysics, and multiphase precipitation); radiative and turbulent heat fluxes (including surface turbulent heat fluxes); and moist convection. If any of these physical processes is switched off, the simulated polar lows tend to be weak or nonexistent. It is also essential that the numerical model's grid resolution is suitable for the scale of the cyclone. Typically horizontal grid squares of 20–50 km are required for a cyclone of a few hundred kilometers and higher resolutions (less than 10 km), if details such as mesoscale fronts are to be simulated. On the other hand, it is also necessary to simulate the evolving synoptic-scale environment as this affects both polar low development and movement. In general, the synoptic-scale flow plays a primary role in steering mesoscale cyclones in a passive manner. However, if two or more polar lows are active within close proximity, it is possible that they will interact and this also affects their movement. Hence forecasting polar low tracks requires both relatively high resolution and large domain sizes.

In an operational context, the simulation and forecasting of polar lows is still problematic; indeed there are examples of misforecasts leading to tragedies as recently as the 2000s. Some state-of-the-art global models, and certainly most regional models, now have sufficient grid resolution for simulation. It is their correct initialization that is the problem. Data assimilation grids tend to be coarser and the observations filtered, to remove what are assumed to be small-scale anomalies, thus many polar lows are not in the initial conditions or the analysis increments when they should be. Furthermore, their relatively rapid development, often from a somewhat random location through convection, means the forecast model may well develop a polar low at the correct time but in the wrong location. There is no doubt that modern data assimilation and forecasting systems are capable of accurate forecasts of polar lows, but they are at the limit of what is possible and misforecasts of location or timing are not infrequent. Regional ensemble prediction systems are now being utilised (e.g. for the Norwegian Sea) which will allow best-track forecasts and provide some statistical forecast information.

Polar Lows and Climate

Their relatively small scale and short lifetime makes polar lows subgrid scale for the vast majority of climate models. Yet their location in the polar and subpolar seas, often close to the sea ice edge, means they are located in a sensitive and rapidly changing part of the climate system. In recent years attention has been focused on the role polar lows play in the climate system and how this may alter in a changing climate.

Case studies of polar lows have often associated them with large air–sea turbulent heat fluxes (as described above) and, given their location in the subpolar seas, there is the potential for this to have a significant impact on the ocean. Recent studies have quantified this impact through ocean modeling experiments using atmospheric forcing fields with and without polar lows. The results demonstrate a dramatic local impact on the

ocean when polar lows are included – a regional surface-layer cooling, an increase in mixed layer depth, a spin-up of the Nordic Seas gyre, and an increase in deep-water formation. The broader-scale impact of polar lows on the ocean is not yet clear.

Complementing earlier satellite-based climatologies, a number of techniques have been developed to quantify the numbers of polar mesoscale cyclones in atmospheric model-based data sets. These include tuning cyclone-tracking algorithms to focus on subsynoptic-scale systems; using proxies such as marine cold-air outbreaks; using a lower–upper temperature threshold to discriminate vortices in cold-air outbreaks; or using a full dynamical downscaling approach (i.e., running a higher resolution nested regional model driven by a global climate model). These approaches have largely corroborated the satellite-based studies, replicating the geographical and seasonal patterns discussed earlier. In addition they have also allowed projections of polar low activity in the future. These projections suggest a poleward migration of polar low activity, following the projected retreat of the sea ice edge, thus a decrease in polar low numbers in the northern midlatitudes and an increase in the sub-Arctic. At this stage, the details of future polar low activity are relatively uncertain.

Introduction

A thermal low (sometimes referred to as a heat low) is a low-pressure area resulting from high temperatures in the lower troposphere caused by a localized area of intense heating at the Earth's surface. Thermal lows occur typically during the summer over subtropical continental areas and are most intense in the desert regions of the world. These regions are characterized by clear skies and a lack of vegetation. Consequently, there is a large diurnal cycle of surface heating, which in turn creates a pronounced diurnal cycle in the intensity of thermal lows, with a maximum intensity (i.e., minimum surface pressure) during the afternoon. Because thermal lows are linked directly to surface properties, they are nonmigratory in nature. Moreover, they do not exhibit any frontal characteristics, nor are clouds or precipitation associated with them.

Since thermal lows arise from surface heating, the maximum amplitudes of temperature and circulation anomalies associated with them are confined to the lower troposphere (i.e., below 5 km or 500 hPa). Most of the desert areas of the world that exhibit strong thermal lows are surrounded by bodies of water. As a result, horizontal heating gradients that develop generate sea and land breezes that influence the thermal-low circulations. In regions away from the equator, the low-level inflow associated with the daytime sea breeze produces, through the action of the Earth's rotation (the Coriolis force), a cyclonic vorticity anomaly in the lower troposphere. The converging air at low levels in the thermal low also produces upward motion in the lower troposphere, but sinking motion occurs aloft. The cyclonic circulation often persists into the nighttime hours above the surface following the development of a shallow, nocturnal temperature inversion. By the morning, subsidence extends all the way down to the surface.

Because of the clear-sky conditions and high surface reflectance (albedo) of the desertlike areas where thermal lows persist, these regions have often been regarded as large-scale radiative energy sinks. However, in some thermal low regions dust is raised from the surface by the intense heating which results in short-wave absorption that makes at least a portion of the thermal low region a radiative energy source.

Geographical Distribution

The strongest thermal lows are located over the great deserts of the world, e.g., the Sahara, Arabian, Kalahari, Australian Great Western Desert, and Mojave/Sonoran Deserts. In these regions the thermal lows are so strong that they appear as closed lows or troughs in the mean-sea-level pressure maps of the summer hemispheres (Figure 1). For example, note the low-pressure troughs over the African Sahara, the Indian subcontinent, and the Southwest US in July and over northern Australia in January. The trough over southern Asia near India in July is

closely associated with cross-equatorial flow over the western Indian Ocean and the Asian summer monsoon.

The locations of thermal lows also correspond to regions of intense surface heating, as can be seen from a map of the global distribution of surface sensible heat flux (Figure 2). The lack of cloudiness, vegetation, and surface moisture in these regions accounts for the large values of surface sensible heat flux. Maximum values upwards of $60\text{--}70\text{ W m}^{-2}$ can be seen in the regions of the major deserts. The close relationship between the thermal lows and surface sensible heat flux patterns indicates a close physical linkage between these two features. Specifically, intense, localized heating warms the lower atmosphere and hydrostatically reduces the surface pressure in that region.

The wind vectors illustrated in Figure 1 show generally confluent surface flow into the thermal low-pressure areas. This flow arises from strong horizontal gradients in the surface sensible heat flux between the desert areas and the surrounding oceans (sensible heat fluxes over the ocean are typically 10 W m^{-2} or less), which drives sea breeze circulations during the daytime hours. At night, a land breeze or offshore surface flow develops, but the intense heating causes the sea breeze to dominate over the land breeze circulation.

Vertical Structure and Energetics

Thermal lows generally develop over arid lands or deserts in the summertime. Figure 3 depicts the thermodynamic structure of the troposphere within a thermal low. The case shown represents a synthesis of data from research aircraft flights over the Arabian desert, although it is typical of other desert regions. To illustrate mixing processes in the atmosphere, vertical profiles of two conserved thermodynamic quantities for dry atmospheric motions, the specific humidity q and the potential temperature θ , are plotted in Figure 3. From the surface to about 5 km or 550 hPa, θ is approximately constant and q decreases with height. This structure is characteristic of deep, continental atmospheric boundary layers containing vigorous, dry convective plumes or thermals. The sharp vertical gradients of q and θ near 5 km represent a transition zone between turbulent air in the atmospheric mixed layer below and laminar flow in the free atmosphere above. The vertical gradients in q and θ in the upper part of the mixed layer are a result of entrainment of drier (lower q) and potentially warmer (higher- θ) air from above into the mixed layer. At night, radiational cooling acts to decrease θ in the lowest kilometer, creating a nocturnal inversion.

Thermal lows typically exist in regions of large-scale subsidence. However, owing to the development of sea breezes during the daytime, the vertical motion in the lowest levels can become upward during the day. This behavior can be seen in Figure 4, which contains profiles of vertical motion at day and night over the Arabian desert. Above 800 hPa there is sinking

Figure 1 Maps of mean sea-level pressure for January and July. Wind vectors for the 1000 hPa level are superimposed. Data are 1980–87 analyses from a forecast model. The contour interval is 5 hPa and the largest vector represents a wind speed of 12 m s^{-1} . Reproduced with permission from Hartmann, D. L., 1994. *Global Physical Climatology*. Academic Press, San Diego, CA.

motion during both day and nighttime hours, although it is weaker during the day owing to short-wave radiative heating of the surface and atmosphere.

The vertical profiles of vertical motion in [Figure 4](#) imply horizontal divergence in the lower to middle troposphere. This divergence is consistent with heating in the lower troposphere that lifts isobaric surfaces above the heat source and produces a midlevel high and coincident outflow of air. This outflow in turn reduces the surface pressure and assists in the inflow of air into the surface low. Part of the outflowing air aloft during the daytime represents the return flow of the sea breeze circulation.

The vertical structure of thermal lows can also be considered from an energy budget perspective. Field studies of thermal

lows show that the raising of dust by daytime heating makes their energetics rather complex. To illustrate this complexity, the vertical structure of the energy balance of the Arabian heat low is shown in [Figure 5](#). This heat low can be characterized as a three-layer system. The lower atmosphere forms a deep mixed layer from the surface to 550 hPa. An upper layer from 550 hPa to the upper boundary is a region where radiative cooling is approximately balanced by adiabatic heating (subsidence warming). A middle layer from 550 to 800 hPa undergoes both sensible and radiative heating. The sensible heating arises from the convergence of eddy heat flux owing to mixed-layer turbulence. The radiative heating results from enhanced daytime shortwave absorption due to a substantial aerosol or

dust loading. The dust is generated locally by daytime vigorous boundary layer thermals and associated gusty surface winds. In the lower layer (surface to 850 hPa) the convergence of eddy heat fluxes dominates radiative cooling, resulting in a net lower-tropospheric warming.

The processes illustrated in Figure 5 indicate that the middle and lower troposphere undergoes a net energy gain due to diabatic processes. The only mechanism to balance this energy gain is a lateral transport of energy out of the region. For the Arabian heat low, the main lateral transport is over the Arabian Sea, where the warm air serves to maintain the West Arabian Sea inversion. This inversion acts to trap water vapor in the lower troposphere as it is carried toward India in the strong south-west summer monsoon flow. This is one mechanism by which thermal lows can have an important influence on surrounding weather patterns.

Dynamics and the Diurnal Cycle

Direct observations indicate that a low-level cyclonic circulation develops typically within thermal lows with a maximum amplitude during the daytime hours. Observations are rather sparse, however, and details of the diurnal cycle of this circulation have not been well documented. Therefore, numerical modeling studies have been used to provide further insight into the dynamics of thermal lows.

Numerical simulations of thermal lows over land surrounded by an ocean show a pronounced diurnal cycle in the circulation patterns. In fact, the circulation cannot be understood without consideration of the diurnal cycle. Simulations show that while the thermal low has a surface pressure minimum in the late afternoon following strong solar heating

Figure 6 Vertical west-east cross-section at 03.00 LST through a thermal low that has formed over a 600×600 km square land area surrounded by ocean in the Northern Hemisphere. Contours indicate meridional (N–S) wind (m s^{-1}). $\otimes$ indicates the center of the maximum southerly flow, $\odot$ the center of the maximum northerly flow. The horizontal arrows denote the centers of maximum zonal (E–W) flow and the vertical arrows indicate the centers of maximum vertical motion. The heavy line indicates the land area. of the land, the relative vorticity is strongest in the early morning hours as a result of a prolonged period of low-level convergence. Thus the thermal low is not approximately in quasi-geostrophic balance.

A depiction of the zonal, meridional, and vertical velocity components at 03.00 LST for an idealized simulation of a thermal low over a $600 \text{ km} \times 600 \text{ km}$ land area surrounded by ocean at 20°N is shown in Figure 6. Low-level convergence, initially developed in connection with a daytime sea breeze, is seen in the early morning hours to evolve into a nocturnal low-level jet. This jet develops as a result of strong nocturnal surface cooling over land. The earth's rotation acting on this circulation generates a cyclonic circulation at low levels, evident in the meridional wind field. The sea breeze return flow aloft is horizontally divergent and it generates an anticyclonic circulation at upper levels, again evident in the meridional wind field. Rising motion occurs at low levels and sinking motion aloft, consistent with the daytime pattern illustrated in Figure 4. The vertical motion over the land eventually reverts to sinking at all levels by 06.00 LST, as in the nighttime curve in Figure 4.

The dynamics of thermal lows can also be considered from a potential vorticity perspective. Observations of the summertime thermal low over the Iberian Peninsula (Spain) show that as an unstable lapse rate forms in the afternoon, a negative potential vorticity anomaly develops over the peninsula. This negative anomaly exists within a large-scale environment of positive

potential vorticity. At night this negative anomaly disappears as stable air develops near the surface due to nocturnal cooling. It has been postulated that the dome of negative potential vorticity associated with the thermal low over the Iberian Peninsula can act to inhibit the development of nearby Algerian lows by increasing the effective interaction distance between upper-level and low-level potential vorticity anomalies.

Introduction

Atmospheric humidity is the amount of water vapor present in the atmosphere. Both the rate of evaporation and the time and place that condensation of cloud water occurs are controlled by humidity. Determination of the atmospheric humidity is important for determining surface evaporation, atmospheric radiative transfer, and certain chemical reactions in the atmosphere.

Vapor Pressure

The partial pressure of water vapor, e , is used as the fundamental measure of water vapor content in the atmosphere. Using Dalton's law of partial pressures, we can use the ideal gas law to write the following expression for water vapor pressure:

$$e = \rho_v R_v T \quad [1]$$

where ρ_v is the water vapor density (often referred to as the absolute humidity), R_v is the specific gas constant for water, and T is the atmospheric temperature. The atmospheric relative humidity is defined as the ratio of the atmospheric vapor pressure to the equilibrium (or saturation) vapor pressure at the temperature of the air, e_s .

To understand what is meant by the saturation vapor pressure, we must first examine the equilibria between phases. Consider a closed container half full of pure water and overlain by dry air. As the water begins to evaporate from the water surface, a small increase in pressure is detected in the air above, resulting from the motion of the water vapor molecules that are added to the air through evaporation. As more and more molecules escape from the water surface in the closed container, the steadily increasing vapor pressure in the air above forces more and more of these molecules to return to the

liquid. Eventually an equilibrium is reached where the number of water vapor molecules returning to the surface balances the number leaving. At that point the air is said to be saturated with water vapor, and the partial pressure of the water vapor is equal to the saturation vapor pressure. The relative humidity is equal to unity (or 100%). If the temperature of the water in the closed container were increased, more water would evaporate before a balance was reached.

A rigorous derivation of the saturation vapor pressure can be accomplished from the second law of thermodynamics. For the liquid–vapor equilibrium, we can write the Clausius–Clapeyron equation as follows,

$$\frac{de_s}{dT} = \frac{L_{lv} e_s}{R_v T^2} \quad [2]$$

where L_{lv} is the latent heat of vaporization (energy per unit mass). At any given temperature, eqn [2] states that there is one and only one pressure at which water vapor is in equilibrium with liquid water, with the saturation vapor pressure increasing approximately exponentially with increasing temperature.

Integration of eqn [2] is made difficult owing to the variation of the latent heat of vaporization with temperature. Additionally, application of the Clausius–Clapeyron equation to determining the saturation vapor pressure in the atmosphere is not strictly valid because of the presence of other gases. Hence empirical values of the saturation vapor pressure are typically used (shown in Table 1).

These empirical values of saturation vapor pressure can be represented by a sixth-order polynomial:

$$e_s = a_1 + \sum_{n=2}^7 a_n (T - T_{tr})^{n-1} \quad [3]$$

where T_{tr} , the so-called 'triple point' of water, is 273.15 K, and the coefficients for the saturation vapor pressure over water and

over ice are as given in [Table 2](#). Note that, at a given temperature, the saturation vapor pressure over ice is smaller than the saturation vapor pressure over liquid water; this is because the latent heat of sublimation (associated with the phase transition between vapor and ice) is larger than the latent heat of vaporization.

Humidity Variables

Values of the saturation vapor pressure are used in the determination of some of the commonly used atmospheric

humidity variables. A wide variety of different humidity variables are used in atmospheric science. The reasons for this are partly historical and partly related to the different methods by which atmospheric humidity is measured. Given information about the ambient atmospheric temperature and pressure, one humidity variable can be used to determine each of the other humidity variables.

The relative humidity, H , is defined as

$$H = \frac{e}{e_s} \quad [4]$$

and H_i , the relative humidity with respect to ice saturation, is defined as

$$H_i = \frac{e}{e_{si}} \quad [5]$$

where e_{si} is the saturation vapor pressure over ice. The relative humidity is the ratio of the actual partial pressure of water vapor in the air to the saturation vapor pressure, and is a function only of e and T . It is commonly multiplied by 100 and expressed as a percentage. Relative humidity can be changed if moisture is added or removed (which changes e), or if the air temperature changes (which changes e_s). At temperatures below 0°C , it is necessary to specify whether the relative humidity is being evaluated relative to the saturation vapor pressure over liquid water or over ice. [Table 3](#) shows that an atmosphere saturated with respect to liquid water is supersaturated with respect to ice, and that the degree of supersaturation increases with the supercooling.

Table 3 Variation of H_i with T for constant $H = 1$

$T(^{\circ}\text{C})$	H	H_i
0	1.0	1.0
-10	1.0	1.10
-20	1.0	1.22
-30	1.0	1.34
-40	1.0	1.47

The water vapor mass mixing ratio, w_v , is the ratio of the mass of water vapor (m_v) present to the mass of dry air (m_d). It is thus defined, after substituting from the ideal gas law [1], as

$$w_v = \frac{m_v}{m_d} = \frac{\rho_v}{\rho_d} = \varepsilon \frac{e}{p - e} \quad [6]$$

where $\varepsilon = M_v/M_d = 0.622$ is the ratio of the molecular weight of water to the molecular weight of the mixture of dry air gases, ρ_d is the density of dry air, and p is total atmospheric pressure.

A value of the saturation mass mixing ratio, w_s , is given by

$$w_s = \varepsilon \frac{e_s}{p - e_s} \quad [7]$$

Expressions for e and e_s from eqns [6] and [7] can be substituted into eqn [4]. Since $p \gg e$ and $p \ll e_s$,

$$H \approx \frac{w_v}{w_s} \quad [8]$$

is an approximate definition of the relative humidity.

The specific humidity is defined as the ratio of the mass of water vapor to the total mass of atmospheric gases. The water vapor mixing ratio can be related to the specific humidity, q_v , as

$$q_v = \frac{m_v}{m_d + m_v} = \varepsilon \frac{e}{p - (1 - \varepsilon)e} = \frac{w_v}{1 + w_v} \quad [9]$$

Since both w_v and q_v are always smaller than 0.04 in the Earth's atmosphere, $q_v \approx w_v$.

The total mass of water vapor in a column of unit cross-sectional area extending from the surface to the top of the atmosphere is called the precipitable water, W_v :

$$W_v = \int_0^{\infty} \rho_v dz \quad [10]$$

where z is height above the Earth's surface. The term 'precipitable water' is used because, if all the vapor in the column were to be condensed into a pool of liquid at the base of the column, the depth of the pool would be equal to W_v/ρ_l , where ρ_l is the density of liquid water. To obtain a relationship between precipitable water and specific humidity, we can write eqn [10] in terms of pressure by incorporating the hydrostatic equation:

$$W_v = \frac{1}{g} \int_p^{p_0} \frac{\rho_v}{\rho_a} dp = \frac{1}{g} \int_p^{p_0} q_v dp \quad [11]$$

where p_0 is the surface pressure, corresponding to $z = 0$ and ρ_a is the air density.

The dew point temperature, denoted by T_D , is defined as the temperature to which moist air must be cooled, the atmospheric pressure and water vapor mixing ratio remaining constant, such that it becomes just saturated with respect to water. Obviously, at T_D the mixing ratio of the air becomes its saturation mixing ratio

$$w_v = w_s(T_D) \quad [12]$$

or equivalently

$$e = e_s(T_D) \quad [13]$$

We can determine the dew point temperature by inverting either eqn [12] or eqn [13], which can be done using eqns [3] and [6]. Although the dew point temperature is expressed in Kelvin, the dew point temperature is a measure not of temperature, but of atmospheric humidity. The term $T - T_D$ is called the dew point depression. Dew point depression is inversely proportional to relative humidity; a relative humidity of 100% corresponds to a dew point depression of zero.

Analogously to the dew point temperature, we define the frost point temperature as the temperature at which ice saturation occurs. The frost point temperature, T_F , is thus defined as

$$e = e_{si}(T_F) \quad [14]$$

or equivalently as

$$w_v = w_{si}(T_F) \quad [15]$$

where w_{si} is the saturation mass mixing ratio over ice. Note that for a given atmospheric mixing ratio, $T_F < T_D$, since $e_{si}(T) < e_s(T)$.

Example Calculations

Air has temperature of 30°C, a relative humidity of 50%, and a pressure of 1000 hPa. This information can be used to determine each of the humidity variables for these conditions:

partial pressure of water vapor, $e = 21.2$ hPa

water vapor mixing ratio, $w_v = 0.0135$

specific humidity, $q_v = 0.0133$

dew point temperature, $T_D = 291.8$ K

Introduction

The thermodynamics of air is complicated by the presence of a mixture of gases, with water vapor having a variable concentration in the atmosphere. The term 'moist air' refers to the dry air gases (predominantly nitrogen and oxygen) plus water vapor. The basic thermodynamics of moist air includes the equation of state, and applications of the first and second laws of thermodynamics to the moist atmosphere (but excludes clouds and the condensation process). These principles of thermodynamics are used to determine how moist air responds to heating and cooling, and how its temperature changes in response to rising and sinking motions. Thermodynamic processes related to condensation, clouds, and precipitation are considered elsewhere in this encyclopedia (see **Thermodynamics: Saturated Adiabatic Processes**).

Equation of State for Air

Except when water vapor is near condensation, air is observed to obey the ideal gas law

$$pV = nR^*T \quad [1]$$

where p is the pressure, V is the volume, n is the number of moles, R^* is the universal gas constant, and T is the temperature. Since the volume and number of moles are not easily measured in the atmosphere, a more useful form of the ideal gas law can be obtained by dividing both sides of eqn [1] by mass, m , yielding

$$p \frac{V}{m} = \frac{n}{m} R^* T \quad [2]$$

Using the definitions of molecular weight, $M = m/n$, and specific volume, $\nu = V/m$, eqn [2] can be written as

$$p\nu = \frac{R^*}{M} T \quad [3]$$

A specific gas constant, R , may be defined as $R = R^*/M$, so that eqn [3] becomes

$$p\nu = RT \quad [4]$$

Strictly speaking, air does not have a molecular weight, since it is a mixture of gases and there is no such thing as an 'air molecule.' However, it is possible to assign an apparent molecular weight to air, since air as a mixture is observed to behave like an ideal gas. By applying Dalton's law of partial pressures, which states that the total pressure exerted by a mixture of gases is equal to the sum of the partial pressures that would be exerted by each constituent alone, it can be determined that each gas individually obeys the ideal gas law

and that the ideal gas law for a mixture of gases can be written as

$$V \sum_j p_j = T \sum_j m_j R_j$$

where p_j , m_j , and R_j are the partial pressure, mass, and specific gas constant, respectively, for the j th constituent, and $\nu = V/m$ has been used. A mean specific gas constant can now be defined as

$$\bar{R} = \frac{\sum_j m_j R_j}{m} \quad [5]$$

The equation of state for the mixture of dry air gases can therefore be written as

$$p\nu = R_d T \quad [6]$$

where R_d is the specific gas constant for dry air. For the gaseous composition of the dry air (which excludes water vapor), a value for R_d is determined to be $287.104 \text{ J K}^{-1} \text{ kg}^{-1}$. The mean molecular weight of the mixture is

$$\bar{M} = \frac{\sum_i n_i M_i}{n} = \frac{m}{n}$$

The mean molecular weight for dry air gases, M_d , is determined to be 28.96 g mol^{-1} .

The equation of state for air is complicated by the presence of water vapor, which has a variable amount in the atmosphere. Assuming that the water vapor is not near condensation, the ideal gas law may be used and is obtained

$$e = \rho_v R_v T \quad [7]$$

where the notation e is commonly used to denote the partial pressure of water vapor and the subscript v denotes the vapor. The specific gas constant for water vapor is $R_v = R^*/M_v = 461.51 \text{ J K}^{-1} \text{ kg}^{-1}$. In a mixture of dry air and water vapor (moist air), the equation of state is

$$p = p_d + e = (\rho_d R_d + \rho_v R_v) T \quad [8]$$

The subscript d denotes the dry air value, and the absence of a subscript denotes the value for the mixture of dry air plus water vapor.

The specific gas constant for moist air is determined from eqn [5] to be

$$R = \frac{(m_d R_d + m_v R_v)}{(m_d + m_v)} \quad [9]$$

where m_d and m_v are the mass of dry air and water vapor, respectively, and $m = m_d + m_v$. The specific humidity, q_v , is defined as

$$q_v = \frac{m_v}{m_v + m_d} \quad [10]$$

so that the specific gas constant for moist air can be written as

$$R = (1 - q_v)R_d + q_vR_v = R_d(1 + 0.608q_v) \quad [11]$$

Incorporating eqn [11] into eqn [8], the equation of state for moist air becomes

$$p_v = R_d(1 + 0.608q_v)T \quad [12]$$

It is awkward to have a variable gas constant, so it is the convention among meteorologists to make the humidity adjustment to the temperature rather than to the gas constant. Thus a virtual temperature, T_v , is defined as:

$$T_v = (1 + 0.608q_v)T \quad [13]$$

so that the ideal gas law for moist air becomes

$$p_v = R_dT_v \quad [14]$$

The virtual temperature may be interpreted as the temperature of dry air having the same values of p and v as the moist air under consideration. Since q_v seldom exceeds 0.02, the virtual temperature correction rarely exceeds more than 2 or 3 °C; however, the small virtual temperature correction has an important effect on buoyancy and hence vertical motions in the atmosphere.

First and Second Laws of Thermodynamics

The first law of thermodynamics is an extension of the principle of conservation of mechanical energy. The conservation principle can be used to define a function U called the internal energy. When an increment of heat dQ is added to moist air, the energy is used to increase the speed of the molecules (i.e., to increase the temperature of the system). The internal energy of a system can increase when heat enters into the system from the surroundings, and/or when work, dW , is done on the system by the surroundings. If dU is taken to denote an increment of internal energy, then

$$dU = dQ + dW \quad [15]$$

This statement is the differential form of the first law of thermodynamics.

The type of work of primary importance in the atmosphere is expansion work, which is defined as

$$dW = -pdV \quad [16]$$

where dV is the differential volume change associated with the work done against the external pressure, p . There are numerous examples of expansion work in the atmosphere, wherein a parcel of air rises in the atmosphere and its pressure decreases and volume increases. Some processes that cause air to rise are (1) orographic lifting, (2) frontal lifting, (3) low-level convergence, (4) buoyant rising of warm air, and (5) mechanical mixing.

Under the conditions of expansion work, the first law of thermodynamics is written as

$$dU = dQ - pdV \quad [17]$$

The first law of thermodynamics can also be written in terms of enthalpy, where enthalpy, H , is defined as $H = U + pV$:

$$dH = dQ + Vdp \quad [18]$$

Equations [17] and [18] are equivalent forms of the first law of thermodynamics. The enthalpy form of the first law is advantageous when considering constant pressure processes, and is more often used in atmospheric science.

A change in heat is related to temperature by

$$dQ_v = mc_vdT$$

for a constant volume process and

$$dQ_p = mc_pdT$$

for a constant pressure process, where c_v is the specific heat at constant volume and c_p is the specific heat at constant pressure. This implies, from eqns [17] and [18], that for ideal gases

$$dU = mc_vdT$$

$$dH = mc_pdT$$

For an ideal gas, it can be shown that $c_p - c_v = R$, where R is the specific gas constant. The magnitude of c_p is greater than c_v because in a constant pressure expansion part of the heat is used for expansion work, while in constant volume heating all of the heat is used to increase the temperature.

The second law of thermodynamics limits both the amount and the direction of heat transfer. According to the second law, a given amount of heat cannot be totally converted into work, thus limiting the amount of heat transfer, and the spontaneous flow of heat must be from a body or substance with a higher temperature to one with a lower temperature, thus stipulating the direction of heat transfer.

Central to understanding the second law of thermodynamics is the concept of reversible and irreversible processes. A reversible process is one in which the system is in an equilibrium state throughout the process. Thus the system passes at an infinitesimal rate through a continuous succession of balanced states that are infinitesimally different from each other. In such a scenario, the process can be reversed, and the system and its environment will return to the initial state. Irreversible processes proceed at finite rates: if the system is restored to its initial state, the environment will have changed from its initial state. The term 'irreversible' does not mean that a system cannot return to its original state, but that the system plus its environment cannot be thus restored. Examples of irreversible processes in the atmosphere are radiative transfer and precipitation.

According to the second law of thermodynamics, there exists an additive function of state known as the equilibrium entropy, which can never decrease in a thermally isolated system. In other words, a thermally isolated system cannot spontaneously regain order which has been lost. The second law may be applied to a system and its surroundings to determine the total entropy change $\Delta\eta_{\text{tot}}$

$$\Delta\eta_{\text{tot}} \geq 0$$

which is known as Clausius' inequality. For the special case of a reversible adiabatic process, the entropy change will be zero in the system alone, $\Delta\eta_{\text{sys}} = 0$, for all reversible adiabatic changes. Reversible adiabatic processes are therefore isentropic.

Consider the first law of thermodynamics in enthalpy form (eqn [18]) for a reversible process:

$$\frac{1}{m}dQ = c_p dT - v dp$$

Reversible heating is an abstract concept, whereby heating of a system occurs infinitesimally slowly through contact with an infinite heat reservoir. For the reversible expansion of an ideal gas, the specific volume may be substituted from the equation of state and divided by temperature:

$$\frac{1}{m} \frac{dQ}{T} = c_p \frac{dT}{T} - R \frac{dp}{p} = c_p d(\ln T) - R d(\ln p) \quad [19]$$

Now, a new thermodynamic state function, the entropy, η , can be defined with units Joules per Kelvin per kilogram, to be

$$d\eta = \left(\frac{dQ}{T} \right)_{\text{rev}} \quad [20]$$

Entropy changes for an ideal gas can be determined from eqns [19] and [20]:

$$\frac{1}{m} d\eta = c_p d(\ln T) - R d(\ln p) \quad [21]$$

Adiabatic Processes in the Moist (but Unsaturated) Atmosphere

The first law of thermodynamics is applied to dry air. The thermodynamic characteristics of dry air have been shown to be:

1. the equation of state is $p\nu = R_d T$;
2. the internal energy is a function of its temperature alone ($dU = m c_v dT$; $dH = m c_p dT$); and
3. the specific heats are related by $c_p - c_v = R_d$.

The first law of thermodynamics for dry air is thus written as

$$m c_v dT = dQ - p dV \quad [22a]$$

$$m c_p dT = dQ + V dp \quad [22b]$$

in internal energy (eqn [22a]) and enthalpy (eqn [22b]) forms.

An adiabatic process is one in which no heat is exchanged between the system and its environment, so that $dQ = 0$. The first law in enthalpy form for an adiabatic expansion of an ideal gas is thus written as

$$c_p dT = v dp \quad [23a]$$

where eqn [23a] has been divided by mass (m) and $v = V/m$ is the specific volume. Considering a reversible adiabatic expansion for an ideal gas, from eqn [23a] and the equation of state eqn [6] is obtained

$$c_p \frac{dT}{T} = R_d \frac{dp}{p} \quad [23b]$$

which may be integrated between an initial and final state to give

$$c_p \ln \left(\frac{T_2}{T_1} \right) = R_d \ln \frac{p_2}{p_1}$$

so that

$$\frac{T_2}{T_1} = \left(\frac{p_2}{p_1} \right)^{R_d/c_p} \quad [24]$$

This relationship holds for reversible, adiabatic processes.

The lifting of air parcels by processes such as orographic lifting, frontal lifting, low-level convergence, and vertical mixing causes pressure to decrease, with a corresponding temperature decrease that is specified by eqn [24]. The lifting of air parcels can be considered a dry adiabatic process as long as condensation does not occur.

If $p_0 = 1000$ hPa is chosen to correspond to a temperature θ , eqn [24] becomes

$$\theta = T \left(\frac{p_0}{p} \right)^{R_d/c_p} \quad [25]$$

where $R_d/c_d = 0.286$ for dry air. The temperature θ is called the potential temperature. It is the temperature a sample of gas would have if it were compressed (or expanded) in an adiabatic reversible process from a given state, p and T , to a pressure of 1000 hPa. θ is a conservative quantity for reversible adiabatic processes in the atmosphere. Consider an atmospheric temperature profile with a lapse rate $\Gamma = 6^\circ \text{C km}^{-1}$. For atmospheric pressures less than 1000 hPa, the potential temperature of a sample of air is greater than the physical temperature, since adiabatic compression must be done to lower the parcel to 1000 hPa. Conversely, the potential temperature of a sample of air with pressure greater than 1000 hPa will be less than the physical temperature. At a pressure level of 1000 hPa, $\theta = T$.

A relationship between entropy and potential temperature for the dry atmosphere is derived by logarithmically differentiating eqn [25]

$$d(\ln \theta) = d(\ln T) - \frac{R_d}{c_p} d(\ln p). \quad [26]$$

Comparison of eqn [26] with eqn [23b] shows that

$$\frac{1}{m} d\eta = c_p d(\ln \theta) \quad [27]$$

This means that for reversible processes in an ideal gas, potential temperature may be considered an alternative variable for entropy.

Equation [25] does not account for water vapor. The specific heat of moist air is

$$c_p = (1 - q_v) c_{pd} + q_v c_{pv} \approx c_{pd} (1 + 0.87 q_v) \quad [28]$$

where the subscripts d and v refer to dry air and water vapor, respectively. The ratio R/c_p for moist air can then be determined from eqn [11] to be

$$\frac{R}{c_p} = \frac{R_d}{c_{pd}} \left(\frac{1 + 0.608 q_v}{1 + 0.87 q_v} \right) \approx \frac{R_d}{c_{pd}} (1 - 0.26 q_v) \quad [29]$$

The potential temperature of moist air then becomes

$$\theta = T \left(\frac{p_0}{p} \right)^{R_d(1 - 0.26 q_v)/c_{pd}} \quad [30]$$

The difference between the dry air and moist air values of θ is generally less than 0.1°C , so that adiabatic expansion or compression of moist air can be treated as if it were dry air. Note that θ is not conserved if a phase change of water occurs.

A virtual potential temperature, θ_v , can also be defined by neglecting the water vapor dependence of the exponent of [eqn \[30\]](#) and replacing the temperature by the virtual temperature

$$\theta_v = T_v \left(\frac{p_0}{p} \right)^{R_d/c_{pd}} \quad [31]$$

If the adiabatic ascent of a parcel of air is considered in the atmosphere, the temperature of the parcel will decrease and the potential temperature will remain the same. The rate of decrease of temperature with height in an adiabatic ascent can be determined by considering the first law in enthalpy form for an adiabatic process ([eqn \[23a\]](#))

$$c_p dT = v dp$$

If it is assumed that the ascent of the parcel does not involve any large vertical accelerations and the hydrostatic relation applies, the hydrostatic relation can be substituted

$$g = \frac{1}{\rho} \frac{\partial p}{\partial z}$$

where ρ is the density of air, into [eqn \[23a\]](#) to give

$$c_p dT = -g dz$$

From the definition of lapse rate, $\Gamma = -dT/dz$, an expression for the dry adiabatic lapse rate, Γ_d , can be written as

$$\Gamma_d = \frac{g}{c_p} \quad [32]$$

which has a value of approximately 9.8 K km^{-1} . Both [eqns \[25\] and \[32\]](#) describe the temperature evolution of a parcel of air in dry adiabatic ascent, but [eqn \[32\]](#) is slightly more restrictive than [eqn \[25\]](#) in that it applies only to a hydrostatic process. The adiabatic lapse rate for moist air differs only slightly from [eqn \[32\]](#) and can be expressed as

$$\Gamma = \frac{g}{c_p(1 + 0.87q_v)}$$

Outside of clouds, diabatic processes (e.g., radiative heating) operate on much longer timescales than the characteristic timescale of vertical displacement of the air parcel. Therefore, the lifting of air parcels by processes such as orographic lifting, frontal lifting, low-level convergence, and vertical mixing can be considered dry adiabatic processes as long as condensation does not occur.

Introduction

Adiabatic processes of moist (but unsaturated) air are described elsewhere in this encyclopedia (*see Thermodynamics: Moist (Unsaturated) Air*), and it is shown that potential temperature remains constant during such processes as long as condensation does not occur. Once condensation occurs in adiabatic cooling associated with ascent, the latent heat of condensation is released. The rate at which saturated air cools as it expands adiabatically is smaller than the rate at which unsaturated air cools adiabatically, because part of the cooling is canceled by the latent heat released during condensation.

The term ‘saturation’ indicates that the atmosphere has a relative humidity (RH) of 100% or greater, with respect to either liquid water or ice (*see Thermodynamics: Humidity Variables*). In saturated air, the thermodynamic system under consideration consists of dry air gases (primarily nitrogen and oxygen), water vapor, and water in a condensed phase (liquid and/or ice particles).

The RH is defined in eqn [1].

$$H = \frac{w_v}{w_s(T)} \quad [1]$$

where w_v is the water vapor mixing ratio (defined as the ratio of the water vapor mass to the dry air mass) and w_s is the saturation mixing ratio (defined as the ratio of the water vapor mass at saturation to the dry air mass). For initially unsaturated air to become saturated, the RH must increase. An increase in RH can be accomplished by increasing the amount of water vapor in the air (i.e., increasing w_v) and/or by cooling the air, which decreases $w_s(T)$. Here, the focus is on adiabatic cooling in rising air as a mechanism for reaching saturation and the subsequent thermodynamic processes associated with the adiabatic cooling of saturated (and cloudy) air.

Adiabatic Processes

Expansion in the atmosphere occurs when air rises due to mechanical lifting (e.g., orographic and frontal), large-scale low-level convergence, turbulent mixing, and buoyancy effects. The expansion is adiabatic if no heat is exchanged between the air and the environment (e.g., radiative transfer).

The entropy equation for an adiabatic process for moist (but unsaturated) air in the absence of condensation is written as eqn [2] (*see Thermodynamics: Moist (Unsaturated) Air*).

$$0 = c_p d(\ln T) - R d(\ln p) \quad [2]$$

where c_p is the specific heat at constant pressure of air, T is temperature, R is the specific gas constant for air, and p is

pressure. From this equation, an expression for the potential temperature, θ (eqn [3]), can be derived.

$$\theta = T \left(\frac{p_0}{p} \right)^{R/c_p} \quad [3]$$

The potential temperature is the temperature air would have if it were compressed (or expanded) in an adiabatic reversible process from a given state, p and T , to a pressure of 1000 hPa. θ is a conservative quantity for reversible adiabatic processes in the atmosphere in the absence of phase changes associated with condensation. From the definition of lapse rate, $\Gamma = -dT/dz$, [1], and the hydrostatic equation, an expression for the dry adiabatic lapse rate, Γ_d , (eqn [4]), can be written.

$$\Gamma_d = \frac{g}{c_p} \approx 9.8^\circ \text{C km}^{-1} \quad [4]$$

As air expands adiabatically and cools, the RH increases as the temperature and saturation mixing ratio decreases. The water vapor mixing ratio remains constant during adiabatic ascent. At some point, the RH reaches 100%, and further cooling results in saturation. (Note: Condensation is initiated typically at relative humidities that slightly exceed 100%.) The temperature at which saturation is reached can be approximated using eqn [5].

$$T_s = \frac{1}{\frac{1}{T - 55} - \frac{\ln H}{2840}} + 55 \quad [5]$$

for initial values of T (in Kelvin) and H . From eqn [3], the saturation pressure, p_s , can be determined as in eqn [6].

$$p_s = p \left(\frac{T_s}{T} \right)^{c_p/R_d} \quad [6]$$

The coordinate (T_s, p_s) is known as the saturation point of the air mass.

During ascent, the water vapor mixing ratio, w_v , remains constant until saturation occurs. The dew point temperature (*see Thermodynamics: Humidity Variables*), however, decreases slightly during the ascent as pressure decreases. The lifting condensation level, z_s , corresponds to the level of the saturation pressure, p_s , which can be approximated as in eqn [7].

$$z_s = 0.12(T_0 - T_{D0}) \quad (\text{km}) \quad [7]$$

This relation is an approximate expression of the height of the lifting condensation level achieved in an adiabatic ascent where T_0 and T_{D0} represent the initial temperature and dew point temperature of the air mass that is being lifted. Calculation of the lifting condensation level provides a good estimate of the cloud base height for clouds that form by adiabatic ascent.

Once saturation occurs, further lifting of the air mass results in condensation. Because of the latent heat released during condensation, the decrease of temperature with height will be smaller than that in dry adiabatic ascent. In addition, the potential temperature, θ , which was conserved in a reversible dry adiabatic ascent, is no longer conserved once condensation occurs.

The adiabatic entropy equation for air with changes of phase between water vapor, liquid, and ice is written as eqn [8].

$$0 = (c_{pd} + w_l c_l) d(\ln T) - R_d d(\ln p_d) - w_v d\left(\frac{A_{lv}}{T}\right) + d\left(\frac{L_{lv} w_v}{T}\right) + w_i d\left(\frac{A_{il}}{T}\right) - d\left(\frac{L_{il} w_i}{T}\right) \quad [8]$$

Here, c_{pd} is the specific heat of dry air, c_l is the specific heat of liquid water, R_d is the specific gas constant for dry air, w_l is the liquid water mixing ratio, w_i is the ice water mixing ratio, w_t is the total water mixing ratio, L_{lv} is the latent heat of vaporization, L_{il} is the latent heat of sublimation, A_{lv} is the affinity for vaporization, and A_{il} is the affinity for freezing. An approximate form of the entropy equation that has no ice phase assumes that condensation occurs at 100% RH, and neglects the specific heats of water relative to dry air, is written as eqn [9].

$$0 = c_{pd} d(\ln T) - R_d d(\ln p) + \frac{L_{lv}}{T} dw_s \quad [9]$$

The saturated adiabatic lapse rate, Γ_s , can be determined from the adiabatic entropy eqn [9], the hydrostatic equation, ideal gas law, the Clausius–Clapeyron equation, and dry adiabatic lapse rate (eqn [10]).

$$\Gamma_s = \Gamma_d \left[\frac{1 + (L_{lv} w_s / R_d T)}{1 + (\varepsilon L_{lv}^2 w_s / c_{pd} R_d T^2)} \right] \quad [10]$$

where $\varepsilon = 0.622$ (the ratio of the molecular weights of water to dry air). The denominator of eqn [10] is larger than the numerator, and thus $\Gamma_s < \Gamma_d$. Table 1 shows the values of Γ_s for selected values of T and p . It is seen that the temperature variation of Γ_s exceeds the pressure variation. At low temperatures and high pressures, Γ_s approaches Γ_d . Values of Γ_s determined from eqn [10] are within about 0.5% of the values determined from a more exact form of the entropy eqn [8]. Because of the approximate nature of eqn [9], Γ_s is sometimes called the pseudoadiabatic lapse rate.

The amount of water condensed in saturated adiabatic ascent, called the adiabatic liquid water content, can be

determined from the adiabatic entropy eqn [9] and the hydrostatic equation (eqn [11]).

$$dw_l = \frac{c_p}{L_{lv}} \left[\frac{dT}{dz} + \frac{g}{c_p} \right] dz \quad [11]$$

Substituting $\Gamma_d = g/c_p$ and $\Gamma_s = -dT/dz$ yields eqn [12]

$$dw_l = \frac{c_p}{L_{lv}} [\Gamma_d - \Gamma_s] dz \quad [12]$$

Integrating eqn [12] from cloud base to height z gives the liquid water content at height z . Because of the complicated form of Γ_s , this equation must be integrated numerically. Integration of eqn [12] shows that the adiabatic liquid water content increases with height above the cloud base and increasing cloud base temperature. Because of the variation of Γ_s with temperature, clouds with warmer bases have larger values of $\Gamma_d - \Gamma_s$ and thus larger values of the adiabatic liquid water content. The adiabatic liquid water content represents an upper bound on the liquid water that can be produced in a cloud by rising motion. Processes such as precipitation and mixing with dry air reduce the cloud liquid water content relative to the adiabatic value.

As adiabatic cooling proceeds, the cloud may eventually cool to the point where ice crystals form. Assuming that a water cloud is present initially, then the formation of ice crystals releases latent heat during fusion. Once the cloud glaciates, it is supersaturated with respect to ice, and deposition occurs on the ice crystals, releasing the latent heat of sublimation, until the ambient RH is at ice saturation. Further cooling will result in the increase of ice water content in the cloud and the release of the latent heat of sublimation into the atmosphere.

Assuming that the thermodynamic system consists of moist air plus liquid water, and that the freezing and subsequent deposition occur isobarically and adiabatically, then the enthalpy of the system will not change during this transformation. This process can be idealized by assuming that first the water freezes at constant temperature and latent heat of freezing is released, then water vapor is deposited on the ice and latent heat of sublimation is released. The temperature change associated with the freezing and subsequent deposition can be approximated from eqn [8] according to eqn [13].

$$\Delta T = \frac{L_{il} w_l + L_{iv} w_s [1 - (e_{si}/e_s)]}{c_p + (\varepsilon w_l L_{iv}^2 / R_d T^2)} \quad [13]$$

This expression gives the increase in temperature due to the freezing of cloud water and the subsequent deposition of water vapor onto the ice crystals. In clouds that cool by adiabatic ascent, the freezing does not occur isobarically, but gradually over a temperature interval.

Once the cloud has glaciated, further adiabatic ascent results in deposition of water vapor onto the ice crystals. Analogously to eqn [10], the ice-saturation adiabatic lapse rate is given by eqn [14], where w_{si} is the saturation mixing ratio with respect to ice and L_{iv} is the latent heat of sublimation.

$$\Gamma_{si} = \Gamma_d \left[\frac{1 + (L_{iv} w_{si} / R_d T)}{1 + (\varepsilon L_{iv}^2 w_{si} / c_{pd} R_d T^2)} \right] \quad [14]$$

The melting process is distinctly different from the freezing process. Melting may occur as ice particles fall to temperatures

Table 1 Γ_s for selected values of temperature and pressure ($K \text{ km}^{-1}$)

T ($^{\circ}C$)	Pressure (hPa)		
	1000	700	500
−30	9.2	9.0	8.7

that are above the melting point. In contrast to freezing, which may be distributed through a considerable vertical depth, melting of ice particles can be quite localized, occurring in a very narrow layer around the freezing point. Cooling of the atmosphere from the melting can result in an isothermal layer near 0 °C. Because of their large size and density, hailstones do not melt at the freezing level in the same manner as a small ice crystal or a snowflake with a low density, but melt over a deeper layer. If atmospheric relative humidities are low in the atmosphere below the melting level, then the melting water will evaporate, cooling the hailstone and retarding the melting.

Conserved Thermodynamic Variables under Saturated Conditions

Potential temperature is a conserved variable in reversible adiabatic processes. The concept of potential temperature becomes less useful when applied to a saturated air, since potential temperature is not conserved during phase changes of water. Derivation of a potential temperature that is conserved in saturated adiabatic ascent eliminates the need to include latent heat source terms in the time-dependent thermodynamic equation.

An analogous variable that is conserved for a cloud in adiabatic ascent can be determined that relates temperature and pressure in a saturated adiabatic process. A conserved temperature for cloud in adiabatic ascent can be derived from eqn [8]. A conserved potential temperature for clouds will obviously be far more complex than the potential temperature derived for a dry adiabatic process, since eqn [8] is considerably more complex than eqn [1]. A number of different conserved potential temperatures have been used for clouds that employ various approximate forms of eqn [8].

The simplest possible case is that in which saturation conditions are maintained, ice is not present, and the heat capacities of the water vapor and condensed water are neglected relative to that of dry air. Using these approximations, the entropy eqn [8] becomes eqn [15].

$$0 = c_{pd}d(\ln T) - R_d d(\ln p) + d\left(\frac{L_{lv}w_s}{T}\right) \quad [15]$$

For a dry adiabatic process, eqn [16] is obtained from eqn [3].

$$c_{pd}d(\ln \theta) = c_{pd}d(\ln T) - R_d d(\ln p) \quad [16]$$

Equating eqn [3] with eqn [16] yields eqn [17].

$$-d\left(\frac{L_{lv}w_s}{T}\right) = c_{pd}d(\ln \theta) \quad [17]$$

This expression is integrated to a height in the atmosphere where all of the water vapor has been condensed out by adiabatic cooling. The corresponding temperature is called the equivalent potential temperature, θ_e , given in eqn [18].

$$\theta_e = \theta \exp\left(\frac{L_{lv}w_s}{c_{pd}T}\right) \quad [18]$$

It is easily determined that $\theta_e > \theta$, which arises from the latent heat released from the condensation of water vapor. Because of the approximations made in eqn [16], the

equivalent potential temperature is only approximately conserved in a saturated adiabatic process. Although approximate, eqn [18] retains the essential physics of the process, whereby the condensation of water vapor provides energy to the moist air and increases its temperature relative to what the temperature would have been in dry adiabatic ascent.

An alternative but analogous potential temperature, the liquid water potential temperature, θ_l , is derived as follows. Equation [16] is written as in eqn [19], where $dw_s = -dw_l$

$$0 = c_{pd}d(\ln T) - R_d d(\ln p) - d\left(\frac{L_{lv}w_l}{T}\right) \quad [19]$$

Then a procedure analogous to the derivation of θ_e write θ_l as in eqn [20] can be followed.

$$\theta_l = \theta \exp\left(-\frac{L_{lv}w_l}{c_{pd}T}\right) \quad [20]$$

One advantage of θ_l over θ_e is that θ_l reverts to θ , the dry potential temperature, in the absence of liquid water.

In the presence of ice, an ice-liquid water potential temperature, θ_{il} , can be derived from the approximate form of eqn [8] given as eqn [21].

$$0 = c_{pd}d(\ln T) - R_d d(\ln p) - d\left(\frac{L_{lv}w_l}{T}\right) - d\left(\frac{L_{iv}w_i}{T}\right) \quad [21]$$

θ_{il} can then be written as in eqn [22].

$$\theta_{il} = \theta \exp\left(-\frac{L_{lv}w_l}{c_{pd}T} - \frac{L_{iv}w_i}{c_{pd}T}\right) \quad [22]$$

The derivation of the ice-liquid water potential temperature implies that it is applicable only under conditions of equilibrium, since the affinity terms were not included. Since ice and liquid are both at equilibrium only at the triple point, use of the ice-liquid water potential temperature is inconsistent physically at temperatures away from the triple point. Nevertheless, the ice-liquid water potential is an economical and not too inaccurate way to treat ice processes in a numerical cloud model.

The entropy potential temperature, θ_η , includes ice processes and is derived from the complete form of the adiabatic entropy eqn [8] as given in eqn [23].

$$\theta_\eta = T\left(\frac{p_0}{p}\right)^{R_d/(c_{pd}+w_l c_l)} \times \exp\left(\frac{(L_{iv} + A_{iv})w_l}{(c_{pd} + w_l c_l)T} - \frac{(L_{il} + A_{il})w_i}{(c_{pd} + w_l c_l)T}\right) \quad [23]$$

The entropy potential temperature is thus the most general potential temperature considered here. Unlike θ_l and θ_{il} , θ_η is applicable to nonequilibrium conditions such as subsaturated or supersaturated environments.

Another moist thermodynamical variable that is often used is the moist static energy, h (eqn [24]).

$$h = (c_{pd} + w_l c_l)T + L_{lv}w_v + (1 + w_l)gz \quad [24]$$

The moist static energy is conserved for adiabatic, saturated, or unsaturated transformations for a closed system in which the pressure change is hydrostatic.

It is important to note the conditions under which θ_e and the other conserved thermodynamic variables are not conserved. Examples include cases where external radiative

heating or conduction takes place, since these alter the entropy. Other examples include atmospheric conditions in which latent heating occurs externally, such as the evaporation of water into air from the ocean or when precipitation falls out.

Synopsis

The thermosphere is the atmospheric region from ~ 85 to ~ 500 km altitude, containing the ionosphere. It is characterized by high temperature and large variability, in response to changes in solar ultraviolet radiation and solar-driven geomagnetic activity. The composition of the lower thermosphere is primarily N_2 and O_2 , similar to the lower and middle atmosphere, but in the upper thermosphere atomic oxygen (O) becomes the dominant gas, due to the importance of photodissociation and molecular diffusion at high altitude. Thermospheric dynamical motions result from complex interactions between solar heating, auroral processes, the resulting pressure gradients, and dissipative processes.

Introduction

The vertical structure of the Earth's atmosphere is categorized by region, based on the vertical structure of the temperature profile. These regions are the troposphere, the stratosphere, the mesosphere, the thermosphere, and the exosphere, and they are separated by boundaries known as the tropopause, the stratopause, the mesopause, and the exobase. The troposphere extends between the ground and about 10 km, where most of the weather that we experience exists. The stratosphere lies between 10 and 50 km, where the ozone layer resides. The mesosphere lies between 50 and 85 km, and the thermosphere begins at ~ 85 km and extends to about 500 km. The exosphere begins near 500 km and extends far out into space. The number densities of the gases in the exosphere are so low that continuum fluid dynamics no longer apply, and gas particles follow ballistic trajectories and orbits.

The thermosphere is the rarefied region of our atmosphere where the temperature increases dramatically with altitude. Many satellites orbit in the thermosphere, experiencing a small drag force from collisions with atoms and molecules that gradually lowers their orbits and eventually causes reentry into the atmosphere. Embedded within the thermosphere is the ionosphere, a weakly ionized plasma that has strong dynamic and electrodynamic interactions with the neutral gases in the thermosphere. Both the thermosphere and ionosphere are strongly influenced by the absorption of solar ultraviolet (UV) radiation. In the polar regions, the thermosphere and ionosphere are affected by auroral processes, that result from the interaction of the solar wind with the Earth's magnetic field. They are also influenced by dynamic processes propagating upward from the lower atmosphere, such as gravity waves, tides, and planetary waves. The combined effect of all of these various forcings gives rise to the great observed variability that exists in the thermosphere/ionosphere system.

Global Mean Structure

The physical and chemical processes that establish the global mean structure of the thermosphere are considerably different from those in the lower atmosphere. The basic structure is

established primarily by the absorption of solar extreme ultraviolet (EUV) radiation at wavelengths shorter than 103 nm, which can ionize and dissociate the gases in the thermosphere, and by the absorption of solar UV radiation at wavelengths between 130 and 175 nm, which can dissociate molecular oxygen. The energetic EUV wavelengths that ionize the gases in the thermosphere create the ionosphere, a weakly ionized plasma that is embedded within and interacts with the neutral gases in the thermosphere. The radiation also dissociates the molecular species of O_2 and N_2 into atomic species of O and N, thus changing the composition of the thermosphere from a molecular atmosphere near the mesopause around 85 km to an atomic atmosphere at the exobase near 500 km. Virtually, all solar photons at wavelengths less than 200 nm are absorbed by the major constituents of the thermosphere, O, O_2 , and N_2 . The neutral gases of the thermosphere are heated locally by the absorption of solar EUV and UV radiation with a heating efficiency of about 33%. The remaining 67% can be either radiated upward to space or downward where it is absorbed in the lower atmosphere. It can also end up as chemical energy from the dissociation of molecular species into atomic species that are transported away from the site of photodissociation. Chemical energy can be transported long distances in the thermosphere because recombination, with the release of chemical energy, is a three-body reaction that requires a high density of neutral particles to proceed rapidly. This occurs mainly in the lower thermosphere near 90 km, where the atomic oxygen density peaks, and therefore the atomic species must be transferred to the lower thermosphere in order to recombine.

The infrared (IR) cooling mechanisms in the thermosphere (5.3 μm emission from NO, 15 μm emission from CO_2 , and 63 μm emission from the fine structure of the ground level of O) are all relatively weak and they are not sufficient to balance the solar heating and maintain radiative equilibrium. The thermosphere is therefore cooled primarily by downward molecular heat conduction above about 120 km and by downward eddy heat conduction to the vicinity of the mesopause where IR cooling becomes sufficiently large to radiate the excess energy to space. Downward thermal conduction implies that the temperature increases with altitude, thus giving a positive temperature gradient with increasing altitude in the

Figure 1 Global mean neutral gas temperature vertical profiles as a function of the solar decimeter radio emission at 10.7 cm wavelength ($F_{10.7}$). The solar decimeter radio emission $F_{10.7}$ (in units of $10^{-22} \text{ W m}^{-2} \text{ Hz}^{-1}$) is an indicator of the solar EUV radiative output.

lower thermosphere. In the upper thermosphere, the molecular thermal conduction coefficient becomes sufficiently large because of the rarefied atmosphere that it dominates the local heating rate. Therefore, the temperature becomes isothermal with altitude at a value called the exospheric temperature.

There is a large variation of temperature and density in the thermosphere because of a large variation of solar EUV and UV radiation with time. In addition to the overall change in solar radiation between solar minimum and maximum, due to the ~ 11 -year solar cycle, there are also shorter term variations on 27-day solar rotation timescales, daily and hourly variations, and impulsive solar flares. Solar spectral irradiance changes influence the thermal, compositional, and dynamic structure of the thermosphere and ionosphere. The global mean temperature profile as a function of the solar activity (represented by the solar 10.7 cm radio emission, which correlates well with the solar EUV flux) is shown in Figure 1. There is an exospheric temperature increase of about 600 K between solar minimum and solar maximum conditions, with a corresponding density increase of about an order of magnitude at 500 km altitude. At short solar EUV wavelengths, less than 30 nm, the EUV emissions that emanate from the Sun's corona are highly variable, increasing by factors of 10–100 between solar minimum and maximum. For wavelengths between 30 and 120 nm, the emissions that emanate from the chromosphere, a more stable region below the corona, are much less variable, showing factors of 2–3. At larger wavelengths, the variability then decreases from a factor of 2 near 100 nm to a factor of 1.1 near 200 nm.

The thermosphere is where the aurora occurs, in the polar regions (Figure 2). The energy and momentum inputs into the ionosphere and thermosphere are governed by the interaction of the highly variable solar wind with the Earth's geomagnetic field. The energetic auroral electrons and protons bombard the high-latitude thermosphere and ionize the neutral gas, dissociate molecular species, and excite various atomic and

Figure 2 This auroral image, displayed as a geographic polar projection covering latitudes greater than 40° , illustrates the large spatial extent of the aurora during the later stages of a magnetic storm. This image was obtained from the University of Iowa's auroral imaging instrumentation on board the NASA satellite Dynamics Explorer 1 using an UV photometer in the 123–165 nm wavelength region.

molecular energy levels that produce the airglow seen visually from the ground and space. There is also a current system of about a million amperes associated with the aurora; the Joule dissipation of these currents strongly heats the thermosphere in the polar regions. The $\mathbf{J} \times \mathbf{B}$ momentum force of this current system can also accelerate the gases in the thermosphere through collisions with the drifting ions. The auroral particle and Joule heating rates are highly variable, on the order of 10^{10} , 10^{11} , and 10^{12} W for quiet, moderate, and highly disturbed auroral conditions, respectively.

Thermosphere Heating and Cooling Processes

To calculate the global average structure of the thermosphere, the thermodynamic and multispecies composition vertical structure equations must be solved simultaneously. The time rate of change of temperature is determined by a balance between downward molecular and eddy heat transport and radiative heat sources and sinks. In the thermosphere, the neutral gas heating rate above 100 km consists of the following 10 component processes: (1) absorption of solar UV radiation in the O_2 Schumann–Runge continuum region (130–175 nm); (2) likewise for the Schumann–Runge bands (175–210 nm); (3) heating by exothermic ion–neutral chemical reactions; (4) heating by exothermic neutral–neutral chemical reactions; (5) heating by elastic and inelastic collisions between ambient electrons, ions, and neutrals; (6) quenching of metastable species, such as $\text{O}(^1\text{D})$, by N_2 and O_2 ; (7) atomic oxygen

recombination; (8) heating by energetic photoelectrons and auroral electrons; (9) Joule dissipation of ionospheric currents in the aurora and dynamo region; and (10) heating by the molecular dissipation of tides, planetary waves, and gravity waves excited in the lower atmosphere that propagate to thermospheric heights. The main cooling processes for the thermosphere are (1) molecular heat conduction; (2) eddy heat conduction; (3) CO_2 $15\ \mu\text{m}$ radiation; (4) NO $5.3\ \mu\text{m}$ radiation; and (5) O $63\ \mu\text{m}$ radiation.

The vertical structure equation for composition includes (1) molecular diffusion; (2) eddy diffusion; (3) composition sources; and (4) composition sinks. A global average vertical structure of temperature and major species number density for solar cycle medium conditions, solar $F_{10.7}$ index ~ 150 , are shown in Figure 3.

Figure 3 (a) A calculated global mean vertical neutral gas temperature profile for solar medium conditions ($F_{10.7} = 150$). (b) The corresponding vertical distribution of the major thermospheric species O , O_2 , and N_2 .

Equations of Motion

The equations of motion governing the dynamics of the thermosphere are the same as those used for predicting weather systems in the lower atmosphere; however, they need to be modified to consider three additional processes that are important at thermospheric heights. These are the viscous force, ion drag force, and pressure forces generated by differences in composition or mean molecular mass.

Kinematic molecular viscosity increases exponentially with altitude by several orders of magnitude in the thermosphere. Its main effect is to transfer momentum between the various altitude regions and thus to smooth out vertical gradients in wind velocity. This viscous force becomes so strong in the upper thermosphere that the winds are uniform with altitude above 300 km. It is also large enough to prevent the development of large horizontal shears and it effectively dissipates any turbulent structures. The viscous force depends upon the vertical wind shear and a characteristic time rate of change associated with viscosity, which is $\sim 10\ \text{s}$ near 200 km, varying exponentially with altitude as the inverse of air density for heights above and below.

The ion drag force is associated with the Ampere acceleration $\mathbf{J} \times \mathbf{B}$ that is important in the thermosphere. It is a collisional interaction of the neutral particles in the thermosphere with the charged particles of the ionosphere. It can be expressed as drag terms that are added to the zonal and meridional momentum equations (eqns [1] and [2]):

$$D_x = \lambda_{xx}(U_I - U_N) + \lambda_{xy}(V_I - V_N) \quad [1]$$

$$D_y = \lambda_{yy}(V_I - V_N) + \lambda_{yx}(U_I - U_N) \quad [2]$$

In these equations, the λ terms are given by eqns [3]–[5]:

$$\lambda_{xx} = \sigma_P B^2 \rho^{-1} \quad [3]$$

$$\lambda_{xy} = \lambda_{yx} = \sigma_H B^2 \rho^{-1} \sin I \quad [4]$$

$$\lambda_{yy} = \sigma_P B^2 \rho^{-1} \sin^2 I \quad [5]$$

In eqns [1]–[5], σ_P and σ_H are the Pedersen and Hall electrical conductivities; B is the magnitude of the magnetic field strength; I is the magnetic dip angle; ρ is the neutral gas density; U_I and V_I are the meridional and zonal ion drift velocities, respectively, and U_N and V_N are the zonal and meridional neutral wind components, respectively; and D_x and D_y are the ion drag terms to be added to the zonal and meridional momentum equations.

The coefficients (λ) are called the ion drag coefficients because the acceleration is a frictional force resulting from ion–neutral collisions. At thermospheric heights above 120 km, the ion–neutral collision frequency is much smaller than the ion gyro frequency (the frequency at which a charged particle spirals around a magnetic field line), and therefore ions are locked to geomagnetic field lines and can only move with them when driven by an electric field. Outside of the auroral zone, electric fields are small and, to a good approximation, the ions can be considered to simply corotate with the magnetic field of the Earth. A neutral wind flowing through the corotating ions experiences a collisional drag that becomes a maximum at the

peak of the ionospheric density layer near 300 km, and this drag provides the main resistance that balances the pressure force. During the day, when the ionization and hence ion drag are large, the wind flows across constant pressure surfaces from the subsolar high-temperature, high-pressure region to the antisolar low-temperature, low-pressure region of night. At night, the density of electrons and ions decays, and the thermospheric pressure forces drive much larger winds because of the reduced ion drag. In the daytime, F-region ionosphere near 300 km, the Pedersen ion drag characteristic inverse time constant can exceed 10^{-3} s^{-1} , which is much greater than the characteristic inverse time constant associated with the inertial and Coriolis terms in the momentum equation. During the day, the Hall ion drag coefficient peaks near 125 km, with a value that can be less than 10^{-4} s^{-1} , roughly comparable with the Coriolis parameter. This acceleration acts perpendicular to the wind vector and is usually opposite in sign to the Coriolis acceleration.

There is also a Joule heating term [6] that is added to the thermodynamic equation:

$$Q_J = \lambda_{xx}(U_I - U_N)^2 + \lambda_{xx}(V_I - V_N)^2 \quad [6]$$

At high magnetic latitudes, large electric fields associated with ion convection can drive large ion drift velocities ($\sim 100\text{--}2000 \text{ m s}^{-1}$) and thus there can be strong acceleration of the neutral winds in the direction of the ion convection pattern. However, the atmosphere will adjust hydrodynamically to this forcing in a complex fashion, either flowing with the drifting ions or building up a back pressure to resist the momentum forcing. Thus the electric fields are both a heat source for the neutral atmosphere, converting the ordered motion of the $\mathbf{E} \times \mathbf{B}$ charged particle drift into increased random thermal motion through collisional processes, and a momentum source ($\mathbf{J} \times \mathbf{B}$) because of the transfer of charged particle momentum to the neutral gas through collisional processes.

An important contrast between the atmosphere above 100 km and the lower atmosphere is that above 100 km the major gaseous atmospheric constituents are no longer uniformly mixed. Above about 160 km, each gas is separately in hydrostatic balance with its own local pressure scale height defined by R^*T/m , where m is the molecular mass of the gas, T is temperature, and R^* is the universal gas constant. This state is referred to as diffusive equilibrium. Between 100 and 160 km, the atmosphere is neither mixed nor in diffusive equilibrium. In particular, molecular oxygen (O_2) is dissociated into atomic oxygen (O) at these levels and the O must be transported downward to below 100 km before the atmosphere is dense enough for chemical recombination to occur. The photoproduction of O from O_2 occurs slowly, with maximum daytime timescales of several days or more, so it cannot drive large diurnal variations in composition. However, transport by large-scale atmospheric motions can be large enough to force significant departures from diffusive equilibrium on both diurnal and longer timescales. Indeed, the mean motion in the thermosphere is a circulation from the summer pole to the winter pole and this circulation transports atomic oxygen from the summer hemisphere, where it is dissociated, to the winter hemisphere, where the maximum densities occur. The simplest feedback of composition on the dynamics is the 'virtual

temperature' effect. That is, the sum of the partial pressures of all the gases taken together is in hydrostatic equilibrium, the vertical variation of geopotential height is proportional to T/M , where M is the mean molecular mass determined by local composition. Dynamic processes tend to eliminate horizontal pressure gradients, or, equivalently, gradients of geopotential height on a constant pressure surface. Hence, motions tend to weaken gradients in T/M with the result that large temperature anomalies are expected to accompany large anomalies in M . Thus, composition – through variations in the mean molecular mass – has an important influence on the pressure force in the thermosphere.

There are other heat and momentum sources acting in the thermosphere. These include heat conduction in the plasma from the magnetosphere to the ionosphere and eventually to the neutral atmosphere, dissipation by thermal conduction, molecular viscosity, and compositional damping of tidal, planetary, and gravity waves that are excited in the lower atmosphere and propagate upward; Joule heating by tide-driven ionospheric current systems; and all sorts of plasma energy and momentum interactions with the neutral atmosphere. The global impact of all of these interactive processes and the coupling of the small-scale phenomena with global scale processes is not completely known.

A schematic of the various physical and chemical processes acting in the thermosphere is shown in Figure 4. The magnetospheric electric field is generated by the interaction of the solar wind with the Earth's magnetic field, which produces a large potential drop across the polar cap. The resulting dawn-to-dusk electric field maps down to thermospheric heights, where it causes the ionospheric ions to drift in an $\mathbf{E} \times \mathbf{B}$ direction and, through collisions with the neutral gas, affects neutral dynamics. To model the thermosphere one needs to consider the complex interactions between neutral and plasma dynamics and electrodynamics. Thus, a general circulation model of the thermosphere must include the interactions with the ionosphere, energy and momentum inputs from the magnetosphere and lower atmosphere, and the electrodynamics interactions throughout the system.

Global Geomagnetic Quiet Time Circulation

The dominant effect driving the winds in the thermosphere is the diurnal variation in the absorption of solar EUV and UV radiation, which heats and expands the dayside thermosphere, creating day-to-night horizontal pressure gradients. In the optically thin upper thermosphere, above 200 km, the solar heating distribution is rather uniform over the dayside, whereas below 200 km the optical depth increases and the solar heating varies with the solar zenith angle. Fourier analysis of the horizontal heating rate distribution shows that the amplitude of wave numbers 1 and 2 are comparable and are generally in phase in the lower thermosphere, but in the upper thermosphere wave number 1 dominates over wave number 2 and they are out of phase. Thus, the upper thermosphere has a diurnal temperature, density, and wind response, whereas the lower thermosphere has a semidiurnal response, as shown in Figure 5.

Figure 4 Schematic of various physical and chemical processes operating in the thermosphere and ionosphere system.

Figure 5 (a) A calculation of temperature in degrees Kelvin (contours) and wind vectors (arrows) in the upper thermosphere near 300 km altitude, for solar medium conditions ($F_{10.7} = 150$). The temperature and wind structure are shown for 0 UTC. The length of the maximum wind vectors represents 450 m s^{-1} . (b) A calculation of temperature and winds in the lower thermosphere near 120 km altitude for the same conditions and time. The length of the maximum wind vector represents 110 m s^{-1} .

Figure 6 (a) A calculation of the ionospheric electric potential in volts over the Northern Hemisphere polar cap. The vectors show the $\mathbf{E} \times \mathbf{B}$ ion drift for moderate levels of auroral activity. The potential drop across the polar cap is 95 kV and the length of the maximum arrow represents a drift speed of 650 m s^{-1} . The electric potential and ion drift pattern are shown for 0 UTC. (b) A calculation of temperature in degrees Kelvin, (contours) and wind vectors (arrows) in the upper thermosphere near 300 km altitude responding to the ion drag forcing shown in (a). The length of the maximum wind vector represents 600 m s^{-1} .

Solar EUV radiation also ionizes the constituents of the thermosphere and produces the ionosphere. Fast photochemical equilibrium exists in the lower ionosphere and produces an electron density distribution that varies with the solar zenith angle. In the upper ionosphere, near 300 km, the ionospheric chemical time constants are much longer, and photochemical equilibrium gives way to complex transport processes that are driven by neutral winds, and by electric fields that are generated in the dynamo region of the thermosphere.

At low- to midlatitudes in the upper thermosphere, the wind flow is, to a first approximation, governed by a balance between the pressure force generated by solar heating and the ion drag and viscous force. The Coriolis force is much smaller, and thus the wind flow is from the high-temperature, high-density region on the dayside to the low-temperature, low-density region of night. This diurnal counter-gradient flow is characteristic of the thermosphere above about 200 km. The magnitude of the wind speed is less on the dayside ($50\text{--}100\text{ m s}^{-1}$) because of increased electron density, and hence ion drag, than at night ($100\text{--}300\text{ m s}^{-1}$), where a significant decrease in electron density occurs because of recombination, significantly reducing the ion drag.

Below 150 km, the ion drag force becomes comparable to the Coriolis force, and the semidiurnal component of thermospheric heating drives a complex semidiurnal oscillation. Below about 100 km, the ion drag force and viscous and compositional forces become small and the more familiar lower atmosphere dynamic equations govern the dynamics of the atmosphere.

Auroral Influences

The basic thermospheric circulation driven by solar heating, shown in [Figure 5](#), is for geomagnetic quiet times when the auroral inputs into the high-latitude thermosphere are small. However, the aurora is seldom quiet for long periods, and in general the interaction of the solar wind with the magnetosphere is highly variable. The aurora particle inputs into the high-latitude thermosphere are electron and proton precipitation, primarily in the auroral oval that surrounds the Earth's magnetic polar cap at about $60\text{--}70^\circ$ geomagnetic latitude in both the Northern and Southern Hemispheres. In addition, the electric fields caused by the interaction of the solar wind with the terrestrial magnetic field drive a two-cell ion drift circulation pattern that is Sun aligned and rotates with the geomagnetic pole around the geographic pole, as shown in [Figure 6](#) for moderate levels of geomagnetic activity. The ion drift imparts a momentum source that causes the neutral gas to follow, but generally lag, the ion drift motion, as also shown in [Figure 6](#). Joule heating causes the temperature to increase in the polar cap. The variability associated with auroral interaction produces large-scale changes in thermospheric circulation, launches large-scale waves that propagate globally, generates major changes in neutral composition, alters the ionospheric dynamic and electrodynamic structure, and produces chemical species such as nitric oxide that alter the radiative balance of the thermosphere. The thermosphere is, thus, in a constant state of agitation, depending upon the magnitude of the auroral inputs, which vary on daily, hourly, and sometimes even faster timescales.

Coupling with the Lower Atmosphere

In addition to solar and auroral forcing, the thermosphere is also affected by dynamics propagating up from the lower atmosphere. The main influence from below is due to atmospheric tides that grow considerably in amplitude as they propagate to high altitudes. The diurnal tide is observed to propagate up to about 110 km in the low-latitude thermosphere before being dissipated by molecular viscosity, thermal conductivity, and ion drag. The semidiurnal tide, with its much longer vertical wavelength, can extend to higher altitudes, reaching about 300 km. Other tidal components are either generated *in situ* or propagate up from the lower atmosphere. Planetary waves have also been observed in the lower thermosphere, especially in the winter high-latitude region, and can have significant effects on ionospheric variability.

Gravity waves generated in the lower atmosphere can propagate up to thermospheric heights and deposit their momentum in the upper mesosphere and lower thermosphere. These waves are filtered by the underlying mean winds, and interact with tides, planetary waves, and other waves generated by processes such as auroral heating. Gravity waves are also damped by thermospheric dissipative processes.

These disturbances or waves from the lower atmosphere greatly influence the lower thermosphere between 90 and 200 km. Above 200 km their influence becomes much smaller because the dynamics are controlled by the solar EUV forcing. Thus, the upper thermosphere has a strong diurnal variation, whereas the lower thermosphere below 200 km experiences semidiurnal variation strongly perturbed by processes propagating upward from the lower atmosphere.

DEDICATION

This second edition of the *Encyclopedia of Atmospheric Sciences* is dedicated to the memory of James Holton who was editor-in-chief of the first edition. He was a great researcher and colleague inspiring an entire generation of atmospheric scientists.

CONTENTS

<i>List of Contributors</i>	xxvii
<i>Preface to the First Edition</i>	xxxix
<i>Preface to the Second Edition</i>	xli
<i>Editor Biographies</i>	xliii
<i>Guide to Using the Encyclopedia</i>	xlvi

VOLUME 1

BASIC ATMOSPHERIC STRUCTURE AND CONCEPTS	1
Beaufort Wind Scale	1
<i>L Hasse</i>	
Wind Chill	7
<i>M Bluestein</i>	
Standard Atmosphere	12
<i>W W Vaughan</i>	
AEROSOLS	17
Aerosol–Cloud Interactions and Their Radiative Forcing	17
<i>U Lohmann</i>	
Aerosol Physics and Chemistry	23
<i>M Kalberer</i>	
Climatology of Stratospheric Aerosols	32
<i>L W Thomason and J-P Vernier</i>	
Climatology of Tropospheric Aerosols	40
<i>N Bellouin and J Haywood</i>	
Dust	48
<i>I N Sokolik</i>	
Observations and Measurements	53
<i>P H McMurry</i>	
Role in Radiative Transfer	66
<i>G A Ban-Weiss, and W D Collins</i>	

Role in Climate Change <i>N Bellouin</i>	76
Soot <i>P Chylek, S G Jennings, and R Pinnick</i>	86
Agricultural Meteorology and Climatology <i>E S Takle</i>	92
ARCTIC AND ANTARCTIC	98
Antarctic Climate <i>J Turner</i>	98
Arctic Climate <i>M C Serreze</i>	107
Arctic Haze <i>L M Russell and G E Shaw</i>	116
AIR SEA INTERACTIONS	
Freshwater Flux <i>J Schulz</i>	122
Momentum, Heat, and Vapor Fluxes <i>P K Taylor</i>	129
Sea Surface Temperature <i>W J Emery</i>	136
Surface Waves <i>A Benilov</i>	144
AVIATION METEOROLOGY	153
Aircraft Emissions <i>R R Friedl</i>	153
Aircraft Icing <i>M K Politovich</i>	160
Aviation Weather Hazards <i>A J Bedard, Jr</i>	166
Clear Air Turbulence <i>G P Ellrod (Retired), J A Knox, P F Lester, and L J Ehernberger (Retired)</i>	177
BIOGEOCHEMICAL CYCLES	187
Sulfur Cycle <i>P Brimblecombe</i>	187
Bromine <i>R von Glasow and C Hughes</i>	194
Heavy Metals <i>T D Jickells and A R Baker</i>	201

Iodine	205
<i>L J Carpenter</i>	
BOUNDARY LAYER (ATMOSPHERIC) AND AIR POLLUTION	220
Overview	220
<i>P J Mason and D J Thomson</i>	
Air Pollution Meteorology	227
<i>X-M Hu</i>	
Coherent Structures	237
<i>F T M Nieuwstadt and J C R Hunt</i>	
Complex Terrain	242
<i>J J Finnigan</i>	
Convective Boundary Layer	250
<i>M A LeMone</i>	
Microclimate	258
<i>M W Rotach and P Calanca</i>	
Modeling and Parameterization	265
<i>A A M Holtslag</i>	
Observational Techniques <i>In Situ</i>	274
<i>E F Bradley</i>	
Observational Techniques: Remote	284
<i>W M Angevine and C J Senff</i>	
Ocean Mixed Layer	290
<i>L Kantha and C A Clayson</i>	
Stably Stratified Boundary Layer	299
<i>L Mahrt</i>	
Surface Layer	305
<i>G L Geernaert</i>	
Urban Heat Islands	310
<i>J C Luvall, D A Quattrochi, D L Rickman, and M G Estes, Jr</i>	
Diurnal Cycle	319
<i>A Betts</i>	
CHEMISTRY OF THE ATMOSPHERE	324
Chemical Kinetics	324
<i>R P Wayne</i>	
Ion Chemistry	333
<i>J L Fox</i>	
Isotopes, Stable	348
<i>C A M Brenninkmeijer</i>	
Laboratory Kinetics	356
<i>D J Donaldson and S N Wren</i>	

Methane <i>E Dlugokencky, and S Houweling</i>	363
Observations for Chemistry (<i>In Situ</i>): Ozone Sondes <i>H G J Smit</i>	372
Observations for Chemistry (<i>In Situ</i>): Particles <i>T Deshler</i>	379
Observations for Chemistry (<i>In Situ</i>): Water Vapor Sondes <i>J B Smith</i>	387
Observations for Chemistry (Remote Sensing): IR/FIR (Satellite, Balloon and Ground) <i>H Fischer and F Hase</i>	401
Observations for Chemistry (Remote Sensing): Lidar <i>G Vaughan</i>	411
Observations for Chemistry (Remote Sensing): Microwave <i>J Waters</i>	418
Principles of Chemical Change <i>R P Wayne</i>	429
Radioactivity: Cosmogenic Radionuclides <i>D Lal</i>	437
Volcanoes: Composition of Emissions <i>M T Coffey and J W Hannigan</i>	446
Tracers <i>K A Boering</i>	450

VOLUME 2

CLIMATE AND CLIMATE CHANGE	1
Overview <i>D L Hartmann</i>	1
Carbon Dioxide <i>C L Sabine and R A Feely</i>	10
Climate Feedbacks <i>A E Dessler and M D Zelinka</i>	18
Climate Prediction: Empirical and Numerical <i>S Hastenrath</i>	26
Climate Variability: Decadal to Centennial Variability <i>D G Martinson</i>	33
Climate Variability: Nonlinear and Random Effects <i>M Ghil</i>	38
Climate Variability: North Atlantic and Arctic Oscillation <i>J W Hurrell</i>	47
Climate Variability: Seasonal and Interannual Variability <i>D S Gutzler</i>	61

Energy Balance Climate Models <i>G R North and K-Y Kim</i>	69
Global Impacts of the Madden–Julian Oscillation <i>C Zhang</i>	73
Greenhouse Effect <i>G R North</i>	80
History of Scientific Work on Climate Change <i>S Weart</i>	87
Intergovernmental Panel on Climate Change <i>K E Trenberth</i>	90
Nuclear Winter <i>A Robock</i>	95
Radiative–Convective Equilibrium Climate Models <i>N O Renno and X Huang</i>	102
Volcanoes: Role in Climate <i>A Robock</i>	105
CLOUDS AND FOG	112
Cloud Modeling <i>W-K Tao and M Moncrieff</i>	112
Contrails <i>P Minnis</i>	121
Cloud Microphysics <i>D Lamb</i>	133
Classification of Clouds <i>A L Rangno (Retiree)</i>	141
Climatology <i>S Warren, R Eastman, and C J Hahn</i>	161
Measurement Techniques <i>In situ</i> <i>D Baumgardner, J-F Gayet, A Korolev, C Twohy, and J Fugal</i>	170
Fog <i>P J Croft and B Ward</i>	180
Noctilucent Clouds <i>G E Thomas</i>	189
Stratus and Stratocumulus <i>R Wood</i>	196
CRYOSPHERE	201
Glaciers, Topography, and Climate <i>A B G Bush and M P Bishop</i>	201
Permafrost <i>T E Osterkamp and C R Burn</i>	208

Sea Ice	217
<i>M C Serreze, F Fetterer, and W F Weeks (Retired)</i>	
Snow (Surface)	227
<i>M Sturm</i>	
DATA ASSIMILATION AND PREDICTABILITY	237
Data Assimilation	237
<i>A C Lorenc</i>	
Ensemble-Based Data Assimilation	241
<i>Z Meng and F Zhang</i>	
Ensemble Prediction	248
<i>R Buizza</i>	
Predictability and Chaos	258
<i>L A Smith</i>	
DYNAMICAL METEOROLOGY	265
Overview	265
<i>J R Holton</i>	
Acoustic Waves	272
<i>K E Gilbert</i>	
Atmospheric Tides	287
<i>J Oberheide, M E Hagan, A D Richmond, and J M Forbes</i>	
Balanced Flow	298
<i>M E McIntyre</i>	
Baroclinic Instability	304
<i>R Grotjahn</i>	
Coriolis Force	313
<i>D W Moore</i>	
Critical Layers	317
<i>P Haynes</i>	
Hamiltonian Dynamics	324
<i>T G Shepherd</i>	
Hydraulic Flow	332
<i>R B Smith</i>	
Inertial Instability	334
<i>J A Knox</i>	
Kelvin–Helmholtz Instability	343
<i>P G Drazin</i>	
Kelvin Waves	347
<i>B Wang</i>	
Kinematics	353
<i>D D Houghton</i>	

Laboratory Geophysical Fluid Dynamics <i>R L Pfeffer</i>	360
Lagrangian Dynamics <i>I Roulstone</i>	369
Potential Vorticity <i>M E McIntyre</i>	375
Primitive Equations <i>A A White and N Wood</i>	384
Quasigeostrophic Theory <i>H C Davies and H Wernli</i>	393
Rossby Waves <i>P B Rhines</i>	404
Solitary Waves <i>J P Boyd</i>	417
Static Stability <i>J A Young</i>	423
Stationary Waves (Orographic and Thermally Forced) <i>S Nigam and E DeWeaver</i>	431
Symmetric Stability <i>H B Bluestein</i>	446
Vorticity <i>J R Holton</i>	451
Wave-CISK <i>C S Bretherton</i>	455
Wave Mean-Flow Interaction <i>M Juckes</i>	458
Waves <i>J R Holton</i>	464

VOLUME 3

ELECTRICITY IN THE ATMOSPHERE	1
Global Electrical Circuit <i>E R Williams</i>	1
Ions in the Atmosphere <i>K L Aplin and R G Harrison</i>	9
Lightning <i>M B Baker</i>	14
Sprites <i>W A Lyons</i>	20
Forensic Meteorology <i>L E Branscome</i>	28

GENERAL CIRCULATION OF THE ATMOSPHERE	33
Overview	33
<i>J M Wallace, D W J Thompson, and P Beresford</i>	
Angular Momentum of the Atmosphere	43
<i>D A Salstein</i>	
Energy Cycle	51
<i>R Grotjahn</i>	
Weather Regimes and Multiple Equilibria	65
<i>F Molteni</i>	
Mean Characteristics	73
<i>R Grotjahn</i>	
Teleconnections	90
<i>S Nigam and S Baxter</i>	
 GLOBAL CHANGE	 110
Climate Record: Surface Temperature Trends	110
<i>P D Jones</i>	
Sea Level Change	121
<i>R S Nerem</i>	
Upper Atmospheric Change	128
<i>R G Roble</i>	
Biospheric Impacts and Feedbacks	132
<i>B A Hungate and G W Koch</i>	
 GRAVITY WAVES	 141
Overview	141
<i>D C Fritts</i>	
Buoyancy and Buoyancy Waves: Optical Observations	153
<i>M J Taylor and W R Pendleton, Jr</i>	
Buoyancy and Buoyancy Waves: Theory	160
<i>T J Dunkerton</i>	
Gravity Waves Excited by Jets and Fronts	164
<i>R Plougonven and F Zhang</i>	
Convectively Generated Gravity Waves	171
<i>T P Lane</i>	
 HYDROLOGY, FLOODS AND DROUGHTS	 180
Overview	180
<i>R C Bales</i>	
Deserts and Desertification	185
<i>V P Tchakerian</i>	
Drought	193
<i>S Quiring</i>	

Flooding	201
<i>C A Doswell III</i>	
Groundwater and Surface Water	209
<i>S Ge and S M Gorelick</i>	
Modeling and Prediction	217
<i>Z Yu</i>	
Palmer Drought Severity Index	224
<i>L Nkemdirim</i>	
Soil Moisture	232
<i>A Robock</i>	
LAND-ATMOSPHERE INTERACTIONS	240
Overview	240
<i>R E Dickinson</i>	
Canopy Processes	244
<i>P D Blanken</i>	
Trace Gas Exchange	256
<i>J N Cape and D Fowler</i>	
LIDAR	262
Atmospheric Sounding Introduction	262
<i>P S Argall and R Sica</i>	
Backscatter	270
<i>C M R Platt and R L Collins</i>	
Differential Absorption Lidar	277
<i>S Ismail and E V Browell</i>	
Doppler	289
<i>R M Hardesty</i>	
Raman	296
<i>D N Whiteman</i>	
Resonance	305
<i>C S Gardner and R L Collins</i>	
Magnetosphere	309
<i>G K Parks</i>	
MESOSCALE METEOROLOGY	316
Overview	316
<i>D J Parker</i>	
Cloud and Precipitation Bands	323
<i>R M Rauber and M Ramamurthy</i>	
Gust Fronts	331
<i>R Rotunno</i>	

Hail and Hailstorms	334
<i>C Knight, N Knight, and H E Brooks</i>	
Mesoscale Convective Systems	339
<i>A Laing</i>	
Microbursts	335
<i>R M Wakimoto</i>	
Severe Storms	361
<i>C A Doswell III</i>	
Waterspouts	369
<i>J H Golden</i>	
Bow Echoes and Derecho	384
<i>M L Weisman</i>	
Density Currents	395
<i>P G Baines</i>	
Convective Storms: Overview	401
<i>M L Weisman</i>	
MESOSPHERE	411
Atomic Species in the Mesopause Region	411
<i>M G Mlynczak and L A Hunt</i>	
Ionosphere	422
<i>M C Kelley</i>	
Metal Layers	430
<i>J M C Plane</i>	
Polar Summer Mesopause	436
<i>R H Varney and M C Kelley</i>	
VOLUME 4	
MIDDLE ATMOSPHERE	1
Planetary Waves	1
<i>A K Smith and J Perlwitz</i>	
Polar Vortex	12
<i>M R Schoeberl and P A Newman</i>	
Quasi-Biennial Oscillation	18
<i>T J Dunkerton, J A Anstey, and L J Gray</i>	
Semiannual Oscillation	26
<i>K Hamilton</i>	
Stratospheric Sudden Warmings	30
<i>A O'Neill, A J Charlton-Perez, and L M Polvani</i>	
Transport Circulation	41
<i>S E Strahan</i>	

Zonal Mean Climatology <i>P Braesicke</i>	50
MOUNTAIN METEOROLOGY	57
Overview <i>R B Smith</i>	57
Cold Air Damming <i>B A Colle</i>	62
Downslope Winds <i>D R Durran</i>	69
Katabatic Winds <i>T R Parish</i>	75
Land and Sea Breezes <i>R A Pielke, Sr</i>	80
Lee Vortices <i>C C Epifanio</i>	84
Lee Waves and Mountain Waves <i>D R Durran</i>	95
Orographic Effects: Lee Cyclogenesis <i>C Schär</i>	103
Valley Winds <i>D Zardi</i>	114
NUMERICAL MODELS	135
Chemistry Models <i>M P Chipperfield and S R Arnold</i>	135
Coupled Ocean-Atmosphere Models: Physical Processes <i>M Zhang</i>	144
General Circulation Models <i>C R Mechoso and A Arakawa</i>	153
Methods <i>J Thuburn</i>	161
Model Physics Parameterization <i>D J Stensrud, M C Coniglio, K H Knopfmeier, and A J Clark</i>	167
Parameter Estimation <i>A Aksoy</i>	181
Parameterization of Physical Processes: Clouds <i>R Forbes, C Jakob, and M Miller</i>	187
Parameterization of Physical Processes: Gravity Wave Fluxes <i>M J Alexander</i>	194
Parameterization of Physical Processes: Turbulence and Mixing <i>A Beljaars</i>	200

Spectral Models <i>F Baer</i>	212
Mesoscale Atmospheric Modeling <i>R A Pielke, Sr</i>	219
Cloud-System Resolving Modeling and Aerosols <i>W-K Tao and T Matsui</i>	222
Large-Eddy Simulation <i>C-H Moeng and P P Sullivan</i>	232
Regional Prediction Models <i>B W Golding</i>	241
Convective Storm Modeling <i>M D Parker</i>	246
OBSERVATIONS PLATFORMS	255
Balloons <i>J-P Pommereau</i>	255
Buoys <i>J M Hemsley</i>	264
Kites <i>B B Balsley</i>	268
Radiosondes <i>W F Dabberdt and H Turtiainen</i>	273
Rockets <i>M F Larsen</i>	285
OCEANOGRAPHIC TOPICS	290
General Processes <i>N C Wells</i>	290
Surface/Wind Driven Circulation <i>R X Huang</i>	301
Thermohaline Circulation <i>R X Huang</i>	315
Water Types and Water Masses <i>W J Emery</i>	329
OPTICS, ATMOSPHERIC	338
Optical Remote Sensing Instruments <i>G G Shepherd</i>	338
Airglow Instrumentation <i>M Conde</i>	346

OZONE DEPLETION AND RELATED TOPICS	353
Long-Term Ozone Changes <i>N R P Harris</i>	353
Ozone as a UV Filter <i>J E Frederick</i>	359
Ozone Depletion Potentials <i>D J Wuebbles</i>	364
Photochemistry of Ozone <i>G K Moortgat and A R Ravishankara</i>	370
Stratospheric Ozone Recovery <i>D J Hofmann and R Müller</i>	380
Surface Ozone Effects on Vegetation <i>M Ashmore</i>	389
Surface Ozone (Human Health) <i>M Lippmann</i>	397
PALEOCLIMATOLOGY	404
Ice Cores <i>E J Steig</i>	404
Varves <i>R Gilbert</i>	411
RADAR	415
Cloud Radar <i>T Uttal</i>	415
Incoherent Scatter Radar <i>M P Sulzer</i>	422
Mesosphere—Stratosphere—Troposphere and Stratosphere—Troposphere Radars and Wind Profilers <i>G Vaughan and D Hooper</i>	429
Meteor Radar <i>N J Mitchell</i>	438
Polarimetric Doppler Weather Radar <i>R J Doviak and R D Palmer</i>	444
Precipitation Radar <i>S E Yuter</i>	455
Synthetic Aperture Radar (Land Surface Applications) <i>R K Vincent</i>	470
VOLUME 5	
RADIATION TRANSFER IN THE ATMOSPHERE	1
Radiation, Solar <i>Q Fu</i>	1

Absorption and Thermal Emission <i>R M Goody and X Huang</i>	5
Cloud-Radiative Processes <i>Q Fu</i>	13
Non-local Thermodynamic Equilibrium <i>M López-Puertas and B Funke</i>	16
Scattering <i>M Mishchenko, L Travis, and A Lacis</i>	27
Ultraviolet Radiation <i>K Stamnes</i>	37
Ultraviolet, Surface <i>R McKenzie and S Madronich</i>	45
SATELLITES AND SATELLITE REMOTE SENSING	51
Aerosol Measurements <i>R A Kahn</i>	51
Earth's Radiation Budget <i>N G Loeb and B A Wielicki</i>	67
GPS Meteorology <i>S S Leroy</i>	77
Measuring Ozone from Space — TOMS and SBUV <i>R D McPeters and R S Stolarski</i>	87
Orbits <i>S Q Kidder</i>	95
Precipitation <i>G Liu</i>	107
Remote Sensing: Cloud Properties <i>P Yang and B A Baum</i>	116
Research <i>M D King</i>	128
Surface Wind and Stress <i>W T Liu</i>	138
Temperature Soundings <i>A Dudhia</i>	145
Water Vapor <i>J E Harries</i>	157
SOLAR SYSTEM/SUN, ATMOSPHERES, EVOLUTION OF ATMOSPHERES	163
Evolution of Earth's Atmosphere <i>Y L Yung, M L Wong, and E J Gaidos</i>	163
Planetary Atmospheres: Mars <i>R M Haberle</i>	168

Planetary Atmospheres: Venus <i>P J Gierasch and Y L Yung</i>	178
Solar Terrestrial Interactions: Climate Impact <i>J D Haigh</i>	183
Solar Winds <i>S T Suess and B T Tsurutani</i>	189
Meteors <i>P Jenniskens</i>	195
STATISTICAL METHODS	201
Data Analysis: Empirical Orthogonal Functions and Singular Vectors <i>C S Bretherton</i>	201
Data Analysis: Time Series Analysis <i>G R North</i>	205
STRATOSPHERIC CHEMISTRY TOPICS	211
Overview <i>J A Pyle</i>	211
Halogens <i>D Toohey</i>	215
Halogen Sources, Anthropogenic <i>A McCulloch and P M Midgley</i>	221
Halogen Sources, Natural (Methyl Bromide and Related Gases) <i>S Yvon-Lewis and J H Butler</i>	228
HO _x <i>T F Hanisco</i>	233
Hydrogen Budget <i>J E Harries</i>	238
Reactive Nitrogen (NO _x and NO _y) <i>Y Kondo</i>	242
Stratospheric Water Vapor <i>K H Rosenlof</i>	250
STRATOSPHERE/TROPOSPHERE EXCHANGE AND STRUCTURE	257
Global Aspects <i>J R Holton</i>	257
Local Processes <i>J F Lamarque and P Hess</i>	262
Tropopause <i>M Dameris</i>	269

SYNOPTIC METEOROLOGY	273
Anticyclones <i>S J Colucci</i>	273
Forecasting <i>D Mansfield</i>	280
Weather Maps <i>R Reynolds</i>	289
Cyclogenesis <i>G J Hakim</i>	299
Extratropical Cyclones <i>A Joly</i>	304
Fronts <i>D M (David) Schultz and W Blumen</i>	337
Fronts in the Lower Stratosphere <i>A L Lang</i>	344
Frontogenesis <i>D M (David) Schultz</i>	353
Jet Streaks <i>P Cunningham and D Keyser</i>	359
Lake-Effect Storms <i>P J Sousounis</i>	370
Polar Lows <i>I A Renfrew</i>	379
Thermal Low <i>R H Johnson</i>	386
THERMODYNAMICS	391
Humidity Variables <i>J A Curry</i>	391
Moist (Unsaturated) Air <i>J A Curry</i>	394
Saturated Adiabatic Processes <i>J A Curry</i>	398
Thermosphere <i>S C Solomon and R G Roble</i>	402
VOLUME 6	
TROPICAL CYCLONES AND HURRICANES	1
Overview and Theory <i>R A Tomas and P J Webster</i>	1

Hurricane Dynamics <i>Y Wang</i>	8
Hurricane Predictability <i>J A Sippel</i>	30
Hurricanes: Observation <i>F D Marks</i>	35
Tropical Cyclogenesis <i>Z Wang</i>	57
Tropical Cyclones and Climate Change <i>T R Knutson</i>	65
Tropical Cyclones in the Western North Pacific <i>J C L Chan</i>	77
Tropical Cyclones: Secondary Eyewall Formation <i>C-C Wu and Y-H Huang</i>	85
TROPICAL METEOROLOGY AND CLIMATE	91
El Niño and the Southern Oscillation: Observation <i>N Nicholls</i>	91
El Niño and the Southern Oscillation: Theory <i>P Chang and S E Zebiak</i>	97
Equatorial Waves <i>M C Wheeler and H Nguyen</i>	102
Hadley Circulation <i>J Lu and G A Vecchi</i>	113
Intertropical Convergence Zone <i>D E Waliser and X Jiang</i>	121
Intraseasonal Oscillation (Madden–Julian Oscillation) <i>R A Madden</i>	132
Madden–Julian Oscillation: Skeleton and Conceptual Models <i>A J Majda and S N Stechmann</i>	137
Monsoon: Overview <i>J Slingo</i>	146
Monsoon: Dynamical Theory <i>P J Webster and J Fasullo</i>	151
Monsoon: ENSO–Monsoon Interactions <i>K-M Lau</i>	165
Tropical Climates <i>S Hastenrath</i>	170
Walker Circulation <i>K-M Lau and S Yang</i>	177

TROPOSPHERIC CHEMISTRY AND COMPOSITION	182

PREFACE TO THE FIRST EDITION

A half century ago the American Meteorological Society published the *Compendium of Meteorology*, which in a single volume of 1334 pages summarized the state of understanding of the atmosphere at that time. A perusal of the contents of that volume indicates that although a broad range of topics was covered, the vast bulk of the volume was devoted to traditional meteorological topics such as atmospheric dynamics, cloud physics, and weather forecasting. Barely 4 percent of the volume was devoted to articles related to atmospheric chemistry or air pollution and, of course, none of the volume was devoted to techniques such as satellites and remote sensing.

As Sir John Mason aptly notes in his foreword to the present work, the atmospheric sciences have expanded in scope enormously over the past 50 years. Topics such as atmospheric chemistry and global climate change, of only marginal interest 50 years ago, are now central disciplines within the atmospheric sciences. Increasingly, developing areas within the atmospheric sciences require students, teachers, and researchers to familiarize themselves with areas far outside their own specialties. This work is intended to satisfy the need for a convenient and accessible references source covering all aspects of atmospheric sciences. It is written at a level that allows undergraduate science and engineering students to understand the material, while providing active researchers with the latest information in the field.

More than 400 scientists, from academia, government, and industry have contributed to the 330 articles in this work. We are very grateful to these authors for their success in providing concise and authoritative summaries of complex subjects. As editors, we have benefited from the chance to learn from these articles, and we believe that all students and active scientists who want to increase their knowledge of the atmosphere will benefit enormously from access to this work.

We are also grateful to the 31 members of the Editorial Advisory Board who have guided us in our coverage of the very broad range of topics represented in this encyclopedia. Their willingness to suggest topics and authors, and to carefully review draft articles has contributed significantly to our success.

The production of this multivolume encyclopedia would not have been possible without the dedicated work of the staff of the Major Reference Works group at Academic Press. We are especially grateful to the Major Reference Work Development Manager, Colin McNeil, who has worked closely with us during the entire process. Finally, we appreciate the liberal use of color figures in the printed encyclopedia.

PREFACE TO THE SECOND EDITION

Since the publication of the first edition of the *Encyclopedia of Atmospheric Sciences*, significant advances in research have been achieved all across the broad and expanding spectrum of the field and related disciplines. In particular, climate science with primary input from the atmospheric research emerges as a new field and integrator of interlocking peripheral disciplines over the last decade. These events have demanded the solicitation of new and updated articles for the 2003 edition. Some articles from the earlier publication were judged to be of such a fundamental and enduring nature that they did not require modification. But huge amounts of new information from Earth-orbiting satellite observatories have brought much new insight to the field. In addition there are new findings in many areas such as the latest simulations of meteorological and climatic processes of interest as well as simulations and observations of the composition and interaction of the field's chemical constituents. While interest in the ozone hole and its ramifications may have reached a plateau, ever more understanding of the stratosphere and its role in climate change emerges. The study of past climates provides new means of testing climate models and theories. In weather prediction we see new progress on how data are to be better assimilated for much improved initialization of the forecast model leading to the promise of more accurate predictions of severe weather and tropical cyclones over longer lead times. These are just a few of the new features of the second edition.

The editors of the second edition are greatly indebted to our predecessors in the first edition. They set the outline of topics and solicited the original authors, while establishing a high standard for the content of this publication. In many cases we decided to reprint those articles or request only minor updates. Nevertheless, many articles in this edition are entirely original, based on which we also made significant reorganization of the content. We are proud of our product and hope it provides the same assistance to students, researchers, and practitioners throughout the science and engineering communities.

EDITOR BIOGRAPHIES

Gerald R North received his PhD in theoretical physics from the University of Wisconsin in 1966. After postdoctoral research at the University of Pennsylvania he became a faculty member in physics at the University of Missouri–St. Louis. He shifted his research focus to climate science research during his sabbatical year at the National Center for Atmospheric Research, where he won the Outstanding Paper Award in 1975. He moved to NASA Goddard Space Flight Center (GSFC) in 1978 where he was awarded the NASA Medal for Research Excellence. During his stay at GSFC, he was the proposer and first study scientist for the Tropical Rainfall Measuring Mission, which was launched in 1997 and is still orbiting in 2014.

He moved to Texas A&M University in 1986 as a university distinguished professor of atmospheric sciences where he served as department head from 1995 to 2003. He has served as editor-in-chief of the *Reviews of Geophysics* and is recognized as one of the most cited authors in geosciences (Web of Science). He has chaired and/or served on a number of national committees and is a Fellow of the American Geophysical Union, American Meteorological Society (AMS) and the American Association for the Advancement of Science, and winner of the Jule Charney Award for Research (AMS).

He has published about 150 refereed papers not including many book chapters and reviews. His books include *Paleoclimatology*, co-authored with Thomas Crowley, and *An Introduction to Atmospheric Thermodynamics* co-authored with Tatiana Erikhimova.

North's interests are focused on the use of mathematical and statistical tools to solve climate problems over a wide range of issues including: analytical solutions of simplified energy balance climate models, use of random field techniques in representing and interpreting climate data and model simulations, detection of deterministic signals in climate change, statistical analysis satellite remote sensing for mission planning and analysis of data, paleoclimate problems using simplified climate models.

John Pyle obtained a BSc in Physics at Durham University before moving to Oxford where he completed a DPhil in Atmospheric Physics, helping to develop a numerical model for stratospheric ozone studies. After a short period at the Rutherford Appleton Laboratory he moved to a lectureship at Cambridge University in 1985. In 2000 he was appointed professor of atmospheric science and since 2007 has been the 1920 professor of physical chemistry. He is a Professorial Fellow at St Catharine's College. He has been a codirector of Natural Environment Research Council's National Centre for Atmospheric Science, where he is currently Chief Scientist.

His research focuses on the numerical modelling of atmospheric chemistry. Problems involving the interaction between chemistry and climate have been addressed; these range from stratospheric ozone depletion to the changing tropospheric oxidizing capacity and have included the environmental impact of aviation, land use change, biofuel technologies, and the hydrogen economy. He has studied palaeochemistry problems as well as the projected atmospheric composition changes during the current century. He has published more than 250 peer reviewed papers.

He played a major role in building an EU stratospheric research programme in the 1990s, coordinating several major field campaigns. He has contributed to all the WMO/UNEP assessments on stratospheric ozone since the early 1980s and is now one of the four international cochairmen

of the Scientific Assessment Panel, responsible for these assessments. He was a convening lead author in the IPCC Special report "Safeguarding the ozone layer and the global climate system," published in 2006.

He was elected Fellow of the Royal Society in 2004 and an American Geophysical Union Fellow in 2011. He was awarded the Cambridge ScD degree in 2012. Other honours and awards include membership of Academia Europaea (1993), Royal Society of Chemistry (Interdisciplinary award, 1991, and John Jeyes lectureship, 2008), and the Royal Meteorological Society Adrian Gill Prize, in 2004.

Fuqing Zhang is a professor with tenure in the Department of Meteorology at the Pennsylvania State University, with a joint appointment in the Department of Statistics, along with an endowed position as the E Willard & Ruby S Miller Faculty Fellow at the College of Earth and Mineral Sciences at the Pennsylvania State University. His research interests include atmospheric dynamics and predictability, data assimilation, ensemble forecasting, tropical cyclones, gravity waves, mountain plains and sea-breeze circulations, warm-season convection, and regional-scale climate. He earned his BS and MS in meteorology from Nanjing University, China in 1991 and 1994, respectively, and his PhD in atmospheric science in 2000 from North Carolina State University.

He spent seven years as an assistant and then associate professor at Texas A&M University before coming to Penn State University as a full professor in 2008. In 2000, he spent a year and a half as a postdoctoral fellow at the National Center for Atmospheric Research. He also held various visiting scholarship appointments at various academic and research institutions including the National Center for Atmospheric Research in Boulder, Colorado; the Navy Research Laboratory in Monterey, California; NOAA/AOML Hurricane Research Division, Miami, Florida; Peking University and Nanjing University, China; the Chinese State Key Laboratory of Severe Weather in Beijing, China; and Laboratoire de Meteorologie Dynamique, École Normale Supérieure in Paris, France.

He has authored/co-authored about 130 peer reviewed journal publications and has given more than 160 keynote speeches or invited talks at various institutions and meetings. He has served as principal investigator/co-principal investigator for 30 federal or state-sponsored research grants. He has chaired/cochaired more than 10 scientific meetings or workshops. He also served on various review or advisory panels for numerous organizations that include National Science Foundation, Office of Naval Research, NASA, NOAA, and National Academies. He has also served as editor of several professional journals including *Monthly Weather Review*, *Science China*, *Atmospheric Science Letter*, *Acta Meteorologica Sinica*, and *Computing in Science & Engineering*.

He has also received numerous awards for his research and service. Notably, in 2007 he received the **Outstanding Publication Award** from the National Center for Atmospheric Research. In 2009, was the sole recipient of the American Meteorological Society's 2009 **Clarence Leroy Meisinger Award** "for outstanding contributions to mesoscale dynamics, predictability, and ensemble data assimilation." Most recently, he received the 2014 American Meteorological Society's **Banner Miller Award** "for valuable insights into incorporating real-time airborne Doppler radar measurements via ensemble data assimilation, leading to improvements in forecasts of tropical cyclone track and intensity."

GUIDE TO USING THE ENCYCLOPEDIA

Structure of the Encyclopedia

The material in the encyclopedia is not arranged by ordinary alphabetical order, but by alphabetical order according to 49 principal topic areas taken to allow all papers belonging to each principal topic to appear together in the same volume. Within each principal subject, article headings are also arranged alphabetically, except where logic dictates otherwise. For example, overview articles appear at the beginning of a section.

There are four features that help you find the topic in which you are interested:

- i. the contents list
- ii. cross-references to other relevant articles within each article
- iii. a full subject index
- iv. contributors

i. Contents List

The contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia. It includes both the volume number and the page number of each entry.

ii. Cross-references

All of the entries in the encyclopedia have been cross-referenced. The cross-references, which appear at the end of an article as a See also list, serve four different functions:

- i. To draw the reader's attention to related material in other entries

- ii. To indicate material that broadens and extends the scope of the article
- iii. To indicate material that covers a topic in more depth
- iv. To direct readers to other articles by the same author(s)

Example

The following list of cross-references appears at the end of the article.

See also: **Biogeochemical Cycles:** Biogeochemistry of Iodine. **Stratospheric Chemistry Topics:** HO_x; Halogen Sources, Natural (Methyl Bromide and Related Gases); Halogens; Hydrogen Budget; Overview; Reactive Nitrogen (NO_x and NO_y).

iii. Index

The index includes page numbers for quick reference to the information you are looking for. The index entries differentiate between references to a whole article, a part of an article, and a table or figure.

iv. Contributors

At the start of each volume there is list of the authors who contributed to that volume.

Introduction

The tropics comprise roughly half the area of the globe and for this reason alone, the motion of the tropical atmosphere represents an important component of the dynamics of the planetary atmosphere. Even if one is primarily interested in the midlatitudes, it is also important to understand the dynamics of the tropics because the circulations at low latitudes can significantly influence the circulations at higher latitudes through various teleconnections. A well-known example of this is the effect that the El Niño Southern Oscillation (ENSO) has on the climate over North America. The influence of one region upon the other can also extend in the opposite direction, with the midlatitudes influencing the tropics. For example, planetary waves sometimes propagate into the tropics from the midlatitudes and excite equatorially trapped waves through lateral forcing and by inducing heating anomalies through enhanced convection.

In the midlatitudes, the rotation of the Earth plays an important role in determining the atmospheric response to forcing. This is also true for the tropics, but the role can be considerably different depending upon the proximity to the Equator. As one approaches the Equator from either pole, the Coriolis parameter $f = 2\Omega \sin(\phi)$ decreases. Here Ω is the rotation rate of the Earth and ϕ is the latitude, and thus the Coriolis parameter is the local vertical component of the Earth's rotation. At 4° latitude f is approximately only 10% as large as it is at 45° latitude. The meridional gradient of f , $\beta = \partial f / \partial y$, is largest at the Equator, and at 10° latitude f increases to be approximately 25% the value at 45° latitude. The Coriolis parameter is zero at the

Equator and it changes sign as one moves across the Equator, from one hemisphere into the other. Many of the differences between the dynamics of the midlatitudes and the dynamics of the tropics can be accounted for by these aspects of behavior of the vertical component of the Earth's rotation as one approaches the Equator.

The diminished size of the Coriolis parameter at low latitudes is responsible for the relatively small geopotential fluctuations – and, through the hydrostatic relation, the temperature fluctuations as well – compared to those in the midlatitudes. Temperature fluctuations are associated with available potential energy, and thus there is considerably less mean and eddy available potential energy in the tropics than in the midlatitudes. As a result, disturbances that grow in the tropics must do so by other means than baroclinic energy conversions, which dominate at higher latitudes. The possible energy sources for tropical disturbances include lateral forcing from the midlatitudes, barotropic energy conversions, and systematic interaction with convective heating such that temperature and heating anomalies are positively correlated. In the next section, we perform a scale analysis to examine the consequences of the magnitude of f being small in the tropics.

A Scale Analysis

Some information about the character of the synoptic-scale motions in the tropics can be obtained by performing a scale analysis of the governing equations. To do this, characteristic

scales are determined for the temporal and spatial variations of the motion based upon observations.

It can be somewhat more intuitive to use a form of the governing equations in which the vertical coordinate has units of length rather than pressure. However, if height is used as the vertical coordinate, density appears explicitly in the equations and this complicates matters rather than simplifying them. A way to avoid this complication is to specify the vertical coordinate as being proportional to the log of the pressure as in eqn [1].

$$z^* \equiv -H \ln \frac{p}{p_s} \quad [1]$$

In eqn [1], p is the pressure, p_s is a standard reference pressure (taken to be 1000 hPa), H is a standard scale height, $H \equiv RT_s/g$, R is the gas constant for dry air, T_s is an average temperature, and g is the gravity force. The units of z^* are the same as those of H , and z^* is approximately equal to the actual height from the surface in the troposphere.

The vertical velocity in this coordinate system is given by eqn [2].

$$w^* \equiv \frac{Dz^*}{Dt} \quad [2]$$

The operator D/Dt is defined in eqn [3], where $\mathbf{V} = iu + jv$, u and v are the zonal and meridional wind components, respectively, and $\nabla = i\partial/\partial x + j\partial/\partial y$.

$$\frac{D}{Dt} \equiv \frac{\partial}{\partial t} + \mathbf{V} \cdot \nabla + \frac{w^* \partial}{\partial z^*} \quad [3]$$

The governing equations are eqns [4], [5], [6], and [7].

$$\left(\frac{\partial}{\partial t} + \mathbf{V} \cdot \nabla + w^* \frac{\partial}{\partial z^*} \right) \mathbf{V} + f \mathbf{k} \times \mathbf{V} = -\nabla \Phi \quad [4]$$

$$\frac{\partial \Phi}{\partial z^*} = \frac{RT}{H} \quad [5]$$

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w^*}{\partial z^*} - \frac{w^*}{H} = 0 \quad [6]$$

$$\left(\frac{\partial}{\partial t} + \mathbf{V} \cdot \nabla \right) T + \frac{w^* N^2 H}{R} = \frac{J}{C_p} \quad [7]$$

These equations represent the horizontal momentum equation, the hydrostatic equation, the conservation of mass, and the conservation of energy, respectively. Here, Φ is the geopotential, J is the heating rate, $N^2 = (R/H)(\partial T/\partial z^* + \kappa T/H)$ is the buoyancy frequency squared, $\kappa \equiv R/C_p$, and C_p is the specific heat for dry air at constant pressure.

For the case of circulations with wavelike structure in space and time, the length and temporal scales are a quarter wavelength (Figure 1). Over a quarter-wavelength interval, a quantity initially with zero amplitude attains (absolute) peak amplitude. In this analysis, we do not provide estimates for the amplitude fluctuations of all quantities appearing in the governing equations. The unspecified quantities are diagnosed from the values provided using the governing equations. We do this because it is instructive to see why, for example, temperature perturbations are relatively small in the tropics. The magnitude of the temperature and vertical velocity perturbations that are diagnosed in the following analysis are in

Figure 1 Schematic diagram showing an example of how the length and amplitude values were chosen for the scale analysis based on disturbances with wavelike structures in space. Time scales were chosen in a similar way, with time replacing distance along the abscissa.

agreement with observations of the type of motions used to determine the values for the scales.

We define characteristic scales for the field variables as:

$D \sim 2.5 \times 10^3 \text{ m}$ vertical depth scale

$L \sim 1.0 \times 10^6 \text{ m}$ horizontal length scale

$U \sim 5.0 \text{ ms}^{-2}$ horizontal velocity scale

$t \sim 1.0 \times 10^5 \text{ s}$ time scale

$f \sim 2.0 \times 10^{-5} \text{ s}^{-1}$ Coriolis parameter at approximately 8°

$\beta = \partial f / \partial y \sim 2.0 \times 10^{-11} \text{ m}^{-1} \text{ s}^{-1}$

$H \sim 8.0 \times 10^3 \text{ m}$ scale height

$N \sim 1.2 \times 10^{-2} \text{ s}^{-1}$ buoyancy frequency

Note that in this analysis, $D < H$.

One consequence of $f = 0$ at the Equator is the existence of disturbances that propagate zonally and whose amplitude decays with distance from the Equator. These are known as equatorially trapped waves. The scale values listed above are representative of equatorially trapped waves with a horizontal wavelength of $4 \times 10^3 \text{ km}$ and vertical wavelength of about 10 km . Numerous theoretical and observational studies confirm their existence in the tropical atmosphere and they are described in detail elsewhere in this volume (see **Tropical Meteorology and Climate: Equatorial Waves**).

We now use these values to estimate the magnitude of the terms appearing in eqn [4], as given by eqns [8] and [11].

$$\left| \frac{\partial \mathbf{V}}{\partial t} \right| \sim \frac{U}{t} \sim 5.0 \times 10^{-5} \text{ ms}^{-2} \quad [8]$$

$$|(\mathbf{V} \cdot \nabla) \mathbf{V}| \sim \frac{U^2}{L} \sim 2.5 \times 10^{-5} \text{ ms}^{-2} \quad [9]$$

$$\left| w^* \frac{\partial \mathbf{V}}{\partial z^*} \right| \sim w^* \frac{U}{D} \sim w^* \times 2.0 \times 10^{-3} \text{ ms}^{-2} \quad [10]$$

$$|f \mathbf{k} \times \mathbf{V}| \sim \frac{U}{f} \sim 1.0 \times 10^{-4} \text{ ms}^{-2} \quad [11]$$

We do not introduce an estimate for the size of w^* from observations and for now we assume that it is small enough so that the vertical advection is considerably less than the other terms. This will turn out to be the case, as will be shown later. The Coriolis term is larger than the other terms on the right-hand side of eqn [4] by a factor of 2 compared to the local time rate of change, and by a factor of 4 compared to the horizontal advection term. For a disturbance with a wavelike horizontal structure, the velocity and the gradient of the velocity are out of phase. Thus, the advection term is likely smaller than estimated in eqn [9]. We assume, then, that the geopotential gradient term is of the same order as the Coriolis term, although it could be somewhat smaller, particularly closer to the Equator. We then have relation [12].

$$\begin{aligned}\nabla\Phi &\sim \frac{\delta\Phi}{L} \sim 1.0 \times 10^4 \text{ m s}^{-2} \\ \Rightarrow \delta\Phi &\sim 100 \text{ m}^2 \text{ s}^{-2}\end{aligned}\quad [12]$$

From eqn [5], we can estimate the temperature perturbation associated with a geopotential perturbation of this size (eqn [13]).

$$T = \frac{H}{R} \frac{\partial\Phi}{\partial z^*} \sim \frac{H}{R} \frac{\delta\Phi}{D} \sim 1.0 \text{ K} \quad [13]$$

The geopotential and the associated temperature perturbations are quite small, about an order of magnitude less than those with the same scale in the midlatitudes. This is a consequence of the Coriolis parameter being an order of magnitude smaller in the tropics than in the midlatitudes.

The terms in the thermodynamic energy equation [7] can now be evaluated as in eqns [14] and [15].

$$\frac{\partial T}{\partial t} \sim \frac{T}{t} \sim 1.0 \times 10^{-5} \text{ K s}^{-1} \quad [14]$$

$$(\mathbf{V} \cdot \nabla)T \sim \frac{UT}{L} \sim 5.5 \times 10^{-6} \text{ K s}^{-1} \quad [15]$$

The local time rate of change is larger than the horizontal advection term by approximately a factor of 2. For the case of baroclinic motions, the temperature perturbations are in quadrature (in the vertical direction) with the horizontal motions, so the horizontal advection of temperature is smaller than the estimate in eqn [15]. We assume that the flow is adiabatic ($J = 0$) and the local time rate of change of temperature is balanced by vertical motion. The balance between the local time rate of change of temperature and vertical motion may then be used to estimate the vertical motion (eqn [16]).

$$\begin{aligned}\frac{\partial T}{\partial t} &\sim \frac{w^* N^2 H}{R} \\ \Rightarrow w^* &\sim \frac{R}{HN^2} \frac{\partial T}{\partial t} \sim 2.5 \times 10^{-3} \text{ m s}^{-1}\end{aligned}\quad [16]$$

Substituting this value into eqn [10], we see that the vertical advection term is small compared to the other terms in eqn [4], as we assumed earlier.

We can now evaluate the magnitude of all of the terms appearing in the continuity equation [6] as in eqns [17], [18], and [19].

$$\frac{\partial u}{\partial x} \sim \frac{\partial v}{\partial y} \sim \frac{U}{D} \sim 5.0 \times 10^{-6} \text{ s}^{-1} \quad [17]$$

$$\frac{\partial w^*}{\partial z^*} \sim \frac{w^*}{D} \sim 1.0 \times 10^{-6} \text{ s}^{-1} \quad [18]$$

$$\frac{w^*}{H} \sim 3.4 \times 10^{-7} \text{ s}^{-1} \quad [19]$$

Comparing eqns [17] and [18], it is clear that there is considerable cancellation between the two horizontal divergence terms. Nevertheless, the horizontal divergence given by their sum is crucial for the existence of equatorially trapped waves. The associated vertical motion and adiabatic temperature changes are necessary to keep the geopotential and temperature fields in hydrostatic balance.

The higher-frequency modes, i.e., the eastward and westward inertio-gravity waves, and the Kelvin waves of all frequencies are highly divergent. To first order, they propagate because of the geopotential changes that result from divergence and convergence. These waves behave like gravity waves in this respect.

The wind fields associated with the lower-frequency modes – the Rossby waves – are much less divergent much more rotational. To first order, they propagate because of vorticity changes that result from the advection of planetary vorticity. This may be illustrated using the equation describing the time rate of change of the vertical component of vorticity. A vorticity equation may be obtained by taking $\mathbf{k} \cdot \nabla$ [4]. Neglecting the terms that are small for synoptic scale motions (vertical advection, tilting, and solenoidal terms) the result is given by eqn [20], where $\zeta = \partial v / \partial x - \partial u / \partial y$.

$$\frac{\partial \zeta}{\partial t} = (\mathbf{V} \cdot \nabla)(\zeta + f) + (\zeta + f)(\nabla \cdot \mathbf{V}) \quad [20]$$

Substituting in the scaling values for the two terms on the right-hand side, we obtain eqns [21] and [22].

$$\begin{aligned}(\mathbf{V} \cdot \nabla)(\zeta + f) &\sim U \left(\frac{U}{L^2}, \beta \right) : \\ \frac{U^2}{L^2} &\sim 2.5 \times 10^{-11} \text{ s}^{-2} \\ U\beta &\sim 1.0 \times 10^{-10} \text{ s}^{-2}\end{aligned}\quad [21]$$

and

$$\begin{aligned}(\zeta + f)(\nabla \cdot \mathbf{V}) &\sim \left(\frac{U}{L}, f \right) \frac{w^*}{D} : \\ \frac{U w^*}{L D} &\sim 5.0 \times 10^{-12} \text{ s}^{-2} \\ f \frac{w^*}{D} &\sim 2.0 \times 10^{-11} \text{ s}^{-2}\end{aligned}\quad [22]$$

Two values are given for each term. The first represents the value obtained using the relative vorticity, ζ , and the second represents the value obtained using the planetary vorticity, f . The second value listed for eqn [21] is appropriate for the entire tropical region because β does not change very much between 30° S and 30° N. In contrast the Coriolis parameter, f , varies considerably within this region. The second value listed for eqn [22] is evaluated at 8° latitude and it approaches zero as $f = \beta y \rightarrow 0$.

For $v \neq 0$ the meridional advection of planetary vorticity is an order of magnitude larger than any of the other terms.

It must be balanced by the time rate of change of vorticity, resulting in wave propagation. This is also true for Rossby waves in the midlatitudes. For the Kelvin wave $v \equiv 0$, the advection of planetary vorticity is zero, and associated vorticity changes, which are small compared to those for the Rossby wave, result only from the divergence term.

The theoretical aspects of equatorially trapped waves are well understood and a number of observational studies have documented and described them (*see Tropical Meteorology and Climate: Equatorial Waves*). They are sometimes systematically associated with convection and, at least in some cases, convective heating acts as a substantial source of energy for the circulations.

The results from this scale analysis depend critically on the value of the depth scale, D . This is because the divergence is proportional to $\delta\Phi/D^2$ and therefore the magnitude of the divergence decreases markedly as D increases. An alternate approach to the one taken in this section is to choose the depth scale to be the same as the scale height. If this is done, one concludes that synoptic-scale motion in the tropics is essentially nondivergent. These circulations cannot convert potential energy to kinetic energy and thus they must be forced laterally from the midlatitudes or locally by barotropic energy conversions from the basic state flow. There is some observational support for the existence of such motion, but not nearly as much as there is for equatorially trapped modes. Perhaps this is because they have not attracted much attention because non-divergent motions would not be associated with precipitation.

The Large-Scale Circulation in the Tropics

What processes determine the structure of the observed large-scale flow in the tropics? Even if one ignores the fact that the tropical circulation and the circulation at higher latitudes influence each other in ways that are sometimes very important, the question posed is still very complex because it depends on processes that have vastly different time and length scales. Also, the forcing functions are not independent of the motion itself.

Latent heating is the dominant source of energy for the tropical circulation, with radiative heating playing an important but secondary role. Therefore, motions on the scale of individual convective clouds and the mesoscale and synoptic-scale systems in which they are sometimes organized are an important part in determining the strength and location of convection that drives the large-scale flow. In addition, the distributions of radiative heating and cooling are strongly influenced by the distribution and the physical characteristics of clouds. The processes that determine the cloud radiative forcing are also significant parts of the answer to the question posed. Inclusion of this level of resolution in a modeling or theoretical study is not very practical, however, and the average effect of convective and radiative processes must be modeled or parameterized in terms of larger-scale variables if they are to be included in studies of the large-scale flow.

The Strength and Location of Convection

As discussed above, tropical motions are driven principally by the latent heat released during convection. The strength and the

location of convective activity, on the other hand, depends strongly on the state of the atmosphere. Different properties of the atmosphere influence convective activity for different reasons. In this section, we consider various processes that influence the strength and location of convection starting at the lower boundary and progressing upward into the free atmosphere.

At the surface, the state of the atmosphere and the state of the ocean and land surface both influence convective activity through their effect on the surface fluxes of latent and sensible heat. The flux of latent heat from the ocean surface supplies the moisture for convective activity. In some instances, this moisture is transported horizontally for large distances before it moves vertically and condenses out of the atmosphere as precipitation. The flux of sensible heat may alter the surface temperature, which in turn may increase the instability of the atmosphere with respect to convection. The physical processes responsible for these fluxes have too small a scale to be explicitly resolved in large-scale modeling and theoretical studies. Data with the resolution necessary to explicitly resolve these processes is rarely available for large-scale analytical studies. In these cases, when knowledge of the fluxes is required, the fluxes must be parameterized in terms of the resolved scale variables. The sensible and latent heat fluxes may be parameterized using a so-called bulk formulation, as in eqns [23] and [24], for example.

$$\frac{H}{\rho C_p} = \overline{w'T'} = C_h U (T_{\text{surface}} - T) \quad [23]$$

$$\frac{E}{\rho L_v} = \overline{w'q'} = C_q U (q_{\text{surface}} - q) \quad [24]$$

In these equations, H is the sensible heat flux, E is the latent heat flux, and, w' , T' , and q' are the sub-grid-scale vertical velocity, temperature, and specific humidity, respectively. C_h and C_q are the transfer coefficients for the sensible and latent heat, which are determined empirically, and $U = (u^2 + v^2)^{1/2}$. T_{surface} is the sea surface temperature (SST) or the land surface temperature and q_{surface} is the saturation mixing ratio calculated using the SST. In the case of land, q_{surface} is calculated in the same way but, depending on the amount of water in the surface layer, it may not be saturated.

In this formulation, the sensible heat flux is proportional to the difference between the surface layer temperature and the atmospheric temperature multiplied by the wind speed. In similar way, the latent heat flux is proportional to the difference between the specific humidity at the surface (which in the case of an ocean surface, is assumed to be saturated at the temperature of the sea surface) and the specific humidity in the atmosphere, multiplied by the wind speed. Feedbacks between the atmosphere and the ocean exist for several reasons. One of the simplest results from the fluxes of latent and sensible heat that cool the ocean near the surface. The cooling reduces the temperature difference at the interface and hence reduces the flux, and there exists a negative feedback.

Another mechanism whereby the atmospheric circulation and the sea surface temperature interact may be explained using the observation that the virtual potential temperature ($\theta_v = T_v(p_0/p)^{\kappa}$), where T_v is the virtual temperature, is approximately constant with height in a well-mixed marine

boundary layer. In addition, observations show that the horizontal variations of θ_v in the atmosphere closely resemble those in the SST. This occurs because shallow convection within the boundary layer mixes air near the surface upward. This temperature and moisture distribution then influences the pressure distribution through the hydrostatic relation. This pressure distribution then determines the boundary layer winds, which may act to transport moisture for some distance. The wind patterns may also result in regions of moisture convergence throughout the depth of the boundary layer and this can have a strong influence on the strength and the location of convection. The convergence does not influence the convection on the scale of individual cumulus clouds but rather on the larger scale, by increasing the low-level moisture over a large region and making it more likely that individual clouds reach the level of free convection.

As evidence in support of this mechanism, observations show that in some locations, such as the western Pacific, warmer SSTs generally associated with stronger convection and the strongest convection is collocated with the warmest SSTs. Such relationships might be expected based upon consideration of eqns [23] and [24] alone. In locations where there exists a moderate pressure gradient across the Equator, however, these relationships break down. These are the

intertropical convergence zones (ITCZs). The SSTs in the ITCZs are observed to be warm but are several degrees cooler than in the west Pacific. In spite of this, the outgoing longwave radiation (OLR) values are comparable in both regions. Also, the convection in the ITCZs is not collocated with the local SST maximum. It has been suggested that this is the result of dynamically driven convergence in the boundary layer that results from the cross-Equator pressure gradient force. A study using a simple model shows that the nonlinear dynamical response to an imposed pressure gradient force directed across the Equator results in a single meridional wind maximum located in the hemisphere with the low-pressure center. The maximum has a narrow meridional extent and is thus associated with a dipole in the convergence field, with the convergence center located between the Equator and the low-pressure center. Some of the results from this study are shown in Figure 2. The solid lines indicate the solution obtained using the full model equations. In this study, the presence of locally anticyclonic absolute vorticity was shown to be important for there to be a single maximum in the meridional wind. When the model was altered to keep the absolute vorticity cyclonic everywhere, the single meridional wind maximum was replaced with two weaker maxima, one in each hemisphere. These results are shown in Figure 2 as dashed lines.

Figure 2 Latitudinal profiles of simulated steady-state parameters obtained using the idealized forcing: (a) geopotential, (b) zonal wind (c) meridional wind, (d) divergence, (e) absolute vorticity, (f) difference between simulated and basic state geopotential. Solid lines indicate the case with the term $v \, du/dy$ included; dashed lines indicate the case with the term omitted. After Tomas R, Holton J, and Webster P (1999).

Finally, divergence in the upper levels of the atmosphere can influence convection. This was recognized early in the modern history of tropical meteorology. The continuity equation requires that vertical motion must exist below and/or above the divergence centers. When the divergence is located in the upper troposphere, the air above is much more statically stable than the air below; thus upward motion from below dominates in the conservation of mass. This upward motion must be balanced by adiabatic cooling for the thermodynamic energy equation to hold. This cooling increases the convective available potential energy in the column. If this cooling occurs low enough in the troposphere, it may also lower the level of free convection.

So far we have discussed various processes whereby the atmosphere and ocean and land exert their influence on the strength and the location of convection and some feedbacks that occur in connection with these processes. This discussion was motivated by the observations that the tropical atmosphere is driven principally by latent heating and that the distribution of latent heating depends strongly on the atmospheric flow. An important question at this point is what the circulation develops in response to convective heating.

Modeling the Response to Imposed Heating

A full account of the large-scale flow in the tropics involves many elements of a complex coupled climate system that includes a wide range of important temporal and spatial scales. Clearly, an approach that involves looking at certain aspects of the tropical circulation in isolation from others can simplify the problem to the point that allows the identification of fundamentally important mechanisms. This strategy has been used successfully to examine the tropical atmosphere's response to imposed heat sources. The approach used in several studies is to construct a simple model of the steady-state atmosphere using the shallow water equations and assuming that the heating is sufficiently small that the motion may be accurately modeled using linear dynamics. The resulting equations after non-dimensionalizing are given as eqns [25], [26], [27], and [28].

$$\varepsilon u - \frac{1}{2}\gamma v = -\frac{\partial p}{\partial x} \quad [25]$$

$$\varepsilon v + \frac{1}{2}\gamma u = -\frac{\partial p}{\partial y} \quad [26]$$

$$\varepsilon p + \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = -Q \quad [27]$$

$$w = -\varepsilon p + Q \quad [28]$$

Here (x, y) is the nondimensional distance in the x (eastward) and y (northward) directions, (u, v) is proportional to the horizontal velocity, p is proportional to the pressure perturbation, and Q is the heating rate, such that if the sign of Q is positive, the signs of u, v, p correspond to those quantities at the surface. The vertical velocity w is given by eqn [28], which is derived from the buoyancy equation. Rayleigh friction (dissipation proportional to speed) and Newtonian cooling (heating or cooling proportional to temperature anomalies relative to the mean temperature) are including using the same coefficient, ε .

The distribution of heating may be specified in terms of the normal modes to these equations, making it possible to obtain analytical solutions. The solution to eqns [25], [26], and [27] for the case of heating centered on the Equator is shown in Figure 3.

One of most striking aspects of this solution is that the influence of the heating on the circulation extends farther eastward than it does westward. Also, the solution to the east of the heating is confined more closely to the Equator than the solution to the west of the heating. Having the analytical solutions to eqns [25], [26], and [27] allows one to interpret this response in terms of the propagation of equatorially trapped waves. The low-level easterlies to the east of the heat source are the result of a Kelvin wave propagating eastward, under the influence of dissipation. The low-level westerlies lying to the west of the heating are the result of a $(n = 1)$ Rossby wave propagating westward under the influence of dissipation. Since the Kelvin wave travels three times faster than the Rossby wave, the easterlies extend farther from the heating than do the westerlies. The Kelvin wave has $v \equiv 0$ and the zonal flow is confined close to the Equator. The $(n = 1)$ Rossby wave

Figure 3 Solution for heating that is symmetric about the Equator in the region $|x| < 2$ for decay factor $\varepsilon = 0.1$. (a) Contours of vertical velocity w (solid contours are 0, 0.3, 0.6, broken contour is -0.1) superimposed on the velocity field for the lower layer. The field is dominated by the upward motion in the heating region, where it has approximately the same shape as the heating function. Elsewhere there is subsidence with the same pattern as the pressure field. (b) Contours of perturbation pressure p (contour interval is 0.3), which is everywhere negative. There is a trough at the Equator in the easterly regime to the east of the forcing region. On the other hand, the pressure in the westerlies to the west of the forcing region, though depressed, is high relative to its value of the Equator. Two cyclones are found to the north-west and south-west flanks of the forcing region. (c) The meridionally integrated flow showing (i) stream function contours, and (ii) perturbation pressure. Note the rising motion in the heating region (where there is a trough) and subsidence elsewhere. After Gill (1980).

horizontal structure consists of two gyres straddling the Equator and rotating in opposite senses.

The distributions of heating and low-level winds are similar to those observed in the Indian and Pacific ocean regions. That is, there is strong convection over the Indonesian region. To the west, over the Indian Ocean, there are westerlies. To the east, over the Pacific Ocean, there are easterlies and the easterlies extend over a much larger distance. The greatest limitation to applying these results to the atmosphere is that they were obtained by specifying the forcing, which is assumed to represent convective heating. As discussed in the previous subsection, the heating depends strongly on the atmospheric circulation. A consistent model of the atmospheric circulation would predict the distribution of heating rather than having it prescribed. Nevertheless, studies of the steady atmospheric response to imposed forcing provide valuable insights to important physical mechanisms that determine horizontal flow patterns and show reasonably good agreement with the broad aspects of the observed circulation.

Hurricane Dynamics

Synopsis

Hurricanes are strong cyclonically rotating systems in the troposphere. A mature hurricane is always well organized with rich structures and unique dynamics. In this article, some key dynamics of hurricanes will be covered, including the basic dynamic structure of a mature hurricane; dynamics of hurricane genesis; dynamics of intensification, maximum potential intensity; and dynamics of hurricane motion. Some other aspects of hurricanes can be found in other relevant articles.

Basic Dynamic Structure

There are different dynamical features in different regions of a mature hurricane (Figure 1). Radially, a hurricane has an eye at its center where little precipitation with almost free or weak radar echoes. The eye is surrounded by outwardly sloped deep cloud wall, named eyewall with heavy precipitation and strongest swirling winds. Immediately outside the eyewall, there are often well-organized narrow rainbands, called inner spiral rainbands where radial shear of swirling wind is extremely large and high wave number asymmetries are often damped effectively. Further outside, namely outside of about 2–3 times of the radius of maximum wind (RMW) are loosely organized rainbands with relatively wide scale in the radial direction and embedded strong convective cells. Those rainbands are often referred to as outer spiral rainbands.

In the vertical, a hurricane consists of three regions. In the lower troposphere, there is a layer immediately above the surface where strong inflow exists, often referred to as the inflow boundary layer. The inflow brings absolute angular momentum (AAM, $M = V_T r + \frac{fr^2}{2}$, where V_T is the tangential wind velocity, r is the radius from the hurricane center, and f is the Coriolis parameter) inward to intensify the tangential wind against the loss of angular momentum to surface friction. The inflow then converges near the RMW and turns upward in the eyewall to support eyewall deep convection. After air in the strong eyewall updrafts reaches the upper troposphere, a small part of the air is

entrained into the eyewall region and is forced to subside and the associated adiabatic warming leads to the formation of a warm-core structure in the mid-upper troposphere. A large part of the air from the eyewall updrafts turns radially outward, forming a relatively deep outflow layer. At some distance away from the eyewall, the outflow will become anticyclonic to conserve AAM and form a large divergent anticyclonic circulation in the upper troposphere. Because of the warm-core structure, the strength of cyclonic circulation decreases with height, leading to the outward tilt of the AAM surface. Since upward motion above the inflow boundary layer follows the AAM surface, the eyewall slopes radially outward with height.

Axisymmetric Structure

To the first order, hurricanes can be viewed as a horizontally quasi-symmetric, primary circulation superimposed by a thermally direct vertical radial, secondary circulation. The primary circulation is nearly in gradient wind balance, namely, centrifugal force and Coriolis force balance the pressure gradient force except for in the frictional boundary layer (Willoughby, 1990):

$$\frac{V_T^2}{r} + fV_T = \frac{1}{\rho} \frac{\partial p}{\partial r} \quad [1]$$

where ρ is the air density and p is the air pressure. The gradient wind (V_G) can be written as

Figure 1 Schematic diagram showing the overall structure of a mature hurricane.

$$V_G = -\frac{fr}{2} + \sqrt{\frac{f^2 r^2}{4} + \frac{1}{\rho} \frac{\partial p}{\partial r}} \quad [2]$$

Observations in hurricanes indicate that gradient wind balance is a good approximation to the actual winds above the boundary layer.

Hurricanes are warm-cored vortices. The radial temperature gradient implies the decrease of tangential wind with height. The vertical shear of tangential wind and the radial temperature gradient satisfy the thermal wind balance. If we write the gradient wind balance in pressure coordinate and use the hydrostatic approximation, we can get

$$\left(f + \frac{2V_T}{r}\right) \frac{\partial V_T}{\partial p} = -\frac{R}{p} \frac{\partial T}{\partial r} \quad [3]$$

where T is the air temperature. Since the vertical shear in tangential wind is not only a function of radial temperature gradient but also the pressure. For the same radial temperature gradient, vertical shear is larger in the upper troposphere than in the lower troposphere and is smaller in the core region than in the region outside the core because of the small radius in the core. This suggests that small hurricanes have a smaller outward slope of the eyewall than the large hurricanes. Thermal wind balance is important to understanding many aspects of hurricane dynamics.

Dynamically, the strong cyclonically swirling flow indicates strong inertial stability (I^2) in the inner core region. In an axisymmetric system, I^2 can be expressed as

$$I^2 = \left(f + \frac{2V_T}{r}\right) \left(f + \frac{1}{r} \frac{\partial r V_T}{\partial r}\right) \quad [4]$$

The high inertial stability implies the resistance to the radial inflow in the boundary layer. As a result, the inertial stability and the strength of the inflow determine where the eyewall upwards would occur and thus the size of the eyewall. Inertial stability also determines the efficiency of warming in the eye forced by diabatic heating in the eyewall (Schubert and Hack,

1982). Since the inertial stability is maximum inside the RMW (Figure 2), diabatic heating inside of the RMW contributes more to the rapid intensification (RI) of a hurricane (Vigh and Schubert, 2009).

Another distinct feature of the strong differential rotation in the inner core of the hurricane vortex is the existence of an annular region immediately outside the RMW. In this annular region, most of the high azimuthal wave number asymmetries would be filamented and thus effectively damped and axisymmetrized. This region is characterized by its strong shear deformation and is often referred to as the filamentation zone. Under the assumption of the nearly circular particle trajectories in a quasi-axisymmetric hurricane vortex, the quantity

$$Q = \frac{1}{4}(S_1^2 + S_2^2 - \zeta^2) \quad [5]$$

measures the relative magnitudes of strain and vorticity and is often called Okubo-Weiss criterion (Guinn and Schubert, 1993), where

$$S_1^2 + S_2^2 = \left(\frac{\partial V_r}{\partial r} - \frac{V_r}{r} - \frac{\partial V_T}{r \partial \lambda}\right)^2 + \left(\frac{\partial V_T}{\partial r} - \frac{V_T}{r} + \frac{\partial V_r}{r \partial \lambda}\right)^2 \quad [6]$$

$$\zeta^2 = \left(\frac{\partial V_T}{\partial r} + \frac{V_T}{r} - \frac{\partial V_r}{r \partial \lambda}\right)^2 \quad [7]$$

where V_r is the radial wind and λ is the azimuth, S_1 is the stretching deformation and S_2 is the shearing deformation, and ζ is the vertical component of relative vorticity.

In regions where $Q < 0$, vorticity dominates strain, trajectories of two neighboring particles do not separate exponentially in time, coherent structures such as mesovortices can survive. This is the case in the eyewall region within the RMW. Conversely, in regions where strain dominates vorticity $Q > 0$, the vorticity gradient intensifies, forming long, thin vorticity gradient sheets across which vorticity changes rapidly along the trajectories. As a result, any asymmetries, particularly those with high azimuthal wave numbers, would be highly distorted

Figure 2 Vertical-radial distribution of inertial stability in a typical hurricane. From Holland, G.J., Merrill, R.T., 1984. On the dynamics of tropical cyclone structural changes. Quarterly Journal of the Royal Meteorological Society 110, 723–745.

(filamented) and axisymmetrized. The axisymmetrization can be measured by the so-called filamentation time that is defined as the e -folding time of the exponential solution in the strain-dominated regions

$$\tau_{\text{fil}} = 2(S_1^2 + S_2^2 - \zeta^2)^{-1/2} \quad \text{for } S_1^2 + S_2^2 > \zeta^2 \quad [8]$$

Since deep, moist convection in the hurricane core region has a typical overturning timescale of about 30 min, the region in which $\tau_{\text{fil}} < 30$ min can be defined as the rapid filamentation zone (RFZ; Rozoff et al., 2006). In the near-core environment of intense tropical cyclones (TCs), the primary flow is quasi-axisymmetric and rapidly rotating. As a result, the shearing deformation generally dominates the stretching deformation in the mid-lower troposphere. Essentially, all fields in the RFZ are generally filamented and deep convection could be highly distorted and even suppressed. Nevertheless, the strain flow in the RFZ outside the RMW provides a favorable environment for

the organized inner spiral rainbands, while the filamentation time provides a quantitative measure of the stabilization/axisymmetrization of high azimuthal wave number asymmetries in the inner core by shearing deformation and filamentation (Wang, 2008). An example for the asymmetric eddy kinetic energy (EKE) in a simulation of an idealized hurricane is shown in Figure 3. In this case, the hurricane has an RMW of about 20 km and RFZ is roughly between radii of 30 and 60 km where relatively small EKE occurs, indicating suppressed asymmetries in the RFZ of the simulated hurricane.

Asymmetric Structure

Although a strong mature hurricane is highly axisymmetric, considerable asymmetric structure can develop as a result of either internal dynamical instability or external forcing, such as environmental vertical wind shear, or both. The asymmetries

are characterized by the so-called vortex Rossby waves (VRWs) in the inner core region and inertia-gravity waves further outside, mesovortices in the eyewall, and polygonal eyewall (Figure 4). In particular, the dynamics of VRWs has been studied comprehensively in the past decade or so. The dynamics of VRWs is very similar to the planetary Rossby waves (MacDonald, 1968; Montgomery and Kallenbach, 1997). The restoring force for the former is the radial gradient of vorticity (or potential vorticity (PV)) while that for the latter is the meridional gradient of Coriolis parameter or equivalently the differential rotation of the earth surface.

Hurricanes are localized vortices with elevated cyclonic PV concentrated in the inner core region near the RMW with large radial gradients. Any radial perturbation of air parcel would experience restoring force due to the presence of PV gradients, and generate edge PV waves. Because their resemblance to the Rossby waves in the mid-latitude large-scale motion, these PV waves are usually termed as VRWs, namely, Rossby-type waves in a circular vortex. The radially outward-propagating VRWs are responsible for initiation of the inner spiral rainbands, and

can affect the structure and intensity of the mean vortex by wave-mean flow interaction. One of the distinct features of Rossby waves in the middle latitude is its quasi-geostrophic balance between mass and circulation fields. The VRWs in hurricanes are dominated by low azimuthal wave numbers in the eyewall with their maximum amplitudes near the RMW and a spiral structure in PV fields. These waves propagate upwind around the eyewall relative to the tangential flow of the azimuthal mean cyclone. The VRWs have a coherent structure in the mid-lower troposphere where the radial PV gradients are large (Chen and Yau, 2001; Wang, 2002a).

The simplest way to understand the basic dynamics of VRWs is based on the linearized nondivergent barotropic vorticity equation below

$$\left(\frac{\partial}{\partial t} + \frac{\bar{V}_T}{r} \frac{\partial}{\partial \lambda} \right) \zeta' - \frac{\partial \psi'}{r \partial \lambda} \frac{d\bar{\eta}}{dr} = 0 \quad [9]$$

where ψ' denotes the perturbation streamfunction, $\zeta' = \nabla^2 \psi'$ the perturbation vorticity, $\bar{v}$ the basic-state tangential velocity at

Figure 4 Moderate Resolution Imaging Spectroradiometer satellite image of Atlantic Hurricane Erin at 1515 UTC 11 September 2001. The right inset shows a magnified image of convoluted clouds in the eye. The left inset shows a smoke and dust plume being carried southward from the collapsed World Trade Center buildings, away from the populated island of Manhattan, in part by Erin's surface flow. radius r , θ the azimuthal angle, t time, ∇^2 the horizontal Laplacian operator, $\bar{\eta} = f + \frac{1}{r} \frac{d(r\bar{V}_T)}{dr}$ the basic-state absolute vertical vorticity, $\bar{V}_T$ the tangential wind of the basic vortex, and f the Coriolis parameter. Given the fact that the outward-propagating waves of eqn [9] often possess radial length scale (l) that is small compared to the characteristic radial scale (L) of the vortex. It is thus reasonable to seek approximate sheared wave solutions near $r = R$ in the form (Montgomery and Kalenbach, 1997)

$$\psi' \approx \Psi(t) \exp\{i[n\lambda + k(t)(r - R) - \Lambda(t)]\} \quad [10]$$

where $\Psi(t)$ is a time-dependent amplitude, $k(t)$ is a time-dependent radial wave number, and $\Lambda(t)$ is a time-dependent phase. In the tightly wound limit, we can assume $kR \gg 1$ without loss of generality. With the Wentzel-Kramers-Brillouin (WKB) approximation for slowly evolving basic state, we can get the following solution for time change of radial wave number

$$\dot{k} = -n\bar{\Omega}' \quad [11]$$

whose integration yields

$$k(t) = k_0 - nt\bar{\Omega}' \quad [12]$$

where k_0 is an initial radial wave number, n is the wave number in the azimuth, and $\bar{\Omega}'(R) = \bar{V}_T'(R)/R$, prime here indicates the derivative respect to radius r , and the solution for the local dispersion relation can be expressed as

$$\omega = n\bar{\Omega} + \frac{n}{R} \frac{\bar{\zeta}'}{(k^2 + n^2/R^2)} \quad [13]$$

for a spectrally localized wave packet whose initial central wave numbers are k_0 and n , respectively. This dispersion relation is analogous to the dispersion relation for nondivergent Rossby waves on a β -plane in a uniform zonal wind. The meridional derivative of planetary vorticity is replaced by the radial derivative of basic-state storm vorticity. For a cyclonic monopole whose basic-state radial vorticity gradient is negative, the dispersion relation predicts that individual waves retrogress relative to the local angular velocity. Unlike unsheared Rossby waves on β -plane, the radial wave number is everchanging for VRWs because of the symmetrizing effect of the vortex. This has fundamental consequences on the kinematics and dynamics of vortex wave packets. Radial and azimuthal phase speeds are given by

$$C_{pr} = \frac{\omega}{k} = \frac{n}{k} \bar{\Omega} + \frac{n}{kR} \frac{\bar{\zeta}'}{(k^2 + n^2/R^2)} \quad [14]$$

$$C_{p\lambda} = \frac{\omega R}{n} = R\bar{\Omega} + \frac{\bar{\zeta}'}{(k^2 + n^2/R^2)} \quad [15]$$

The speed and direction of energy propagation is controlled by the group velocity whose radial and azimuthal components are given by

$$C_{gr} = \frac{\partial \omega}{\partial k} = \frac{-2kn\bar{\zeta}'}{R(k^2 + n^2/R^2)^2} \quad [16]$$

$$\begin{aligned} C_{g\lambda} &= \frac{\partial \omega}{\partial (n/R)} \\ &= R\bar{\Omega} + \frac{\bar{\zeta}'}{(k^2 + n^2/R^2)^2} \left[k_0^2 - \frac{n^2}{R^2} \left(1 + t^2 R^2 \bar{\Omega}'^2 \right) \right] \end{aligned} \quad [17]$$

Note that in eqns [13]–[17], k is given by eqn [12]. Since a trailing spiral wave is associated with positive k , it corresponds to positive radial group velocity and thus an outward propagation of the wave energy. As the packet propagates outward it is continuously slowed by the shearing effect that increases its radial wave number. Since for large k the radial group velocity goes as $O(k^{-3})$, the shearing effect eventually dominates and radial propagation ceases. Such a location is referred to as stagnation radius. For the instantaneous position of a wave packet, the stagnation radius r_s , on letting $t \rightarrow \infty$, can be given by

$$r_s = R + \frac{\bar{\zeta}'}{R\bar{\Omega}'} \frac{1}{(k_0 + n^2/R^2)} \quad [18]$$

The existence of a stagnation radius implies that these waves are confined to the near-vortex region and cannot radiate to infinity. Their dynamics is thus distinct from that of gravity-inertia waves that, in the absence of critical levels, radiate to infinity.

On repeating the above WKB analysis, the dispersion relation for an isolated wave packet in a divergent barotropic flow is only slightly modified by the variable deformation radius. In that case, the instantaneous wave frequency becomes

$$\omega = n\bar{\Omega} + \frac{n}{R} \frac{\bar{\xi}}{\bar{q}} \frac{\bar{q}'}{(k^2 + n^2/R^2 + \gamma^2)} \quad [19]$$

where $\bar{\xi} = f + 2\bar{V}_T/r$ is the inertia parameter, $\bar{q} = \bar{\eta}/(g\bar{H})$ is the basic-state PV, with $\bar{\eta} = f + (1/r)d(r\bar{V}_T)/dr$ being the absolute vorticity, $\gamma^2 = \bar{\eta}\bar{\xi}/(g\bar{H})$ is the square of the inverse of the local Rossby radius of deformation; the subscript zero has the same meaning as those in eqn [13]. The corresponding expressions for radial and azimuthal phase speeds are

$$C_{pr} = \frac{\omega}{k} = \frac{n}{k} \bar{\Omega} + \frac{n}{kR} \frac{\bar{\xi}}{\bar{q}} \frac{\bar{q}'}{(k^2 + n^2/R^2 + \gamma^2)} \quad [20]$$

$$C_{p\lambda} = \frac{\omega}{(n/R)} = R\bar{\Omega} + \frac{\bar{\xi}}{\bar{q}} \frac{\bar{q}'}{(k^2 + n^2/R^2 + \gamma^2)} \quad [21]$$

Corresponding expressions for the radial and azimuthal group velocities are

$$C_{gr} = \frac{\partial \omega}{\partial k} = \frac{-2kn}{R} \frac{\bar{\xi}}{\bar{q}} \frac{\bar{q}'}{(k^2 + n^2/R^2 + \gamma^2)^2} \quad [22]$$

$$\begin{aligned} C_{g\lambda} &= \frac{\partial \omega}{\partial (n/R)} = R\bar{\Omega} + \frac{\bar{\xi}}{\bar{q}} \frac{\bar{q}'}{(k^2 + n^2/R^2 + \gamma^2)^2} \\ &\quad \times \left[k_0^2 + \gamma^2 - \frac{n^2}{R^2} \left(1 + t^2 R^2 \bar{\Omega}'^2 \right) \right] \end{aligned} \quad [23]$$

The stagnation radius follows upon integrating C_{gr} with respect to time and letting $t \rightarrow \infty$:

$$r_s = R + \frac{\bar{\xi}\bar{q}'}{\bar{q}R\bar{\Omega}'} \frac{1}{(k_0 + n^2/R^2 + \gamma^2)} \quad [24]$$

The dependence of r_s on γ^2 indicates a tendency for the vorticity bands to remain closer to the core with increasing γ^2 .

These can be understood from the local dispersion relation for VRWs modified to include the baroclinic effect as given below (see Möller and Montgomery, 2000 for details).

$$\omega = n\bar{\Omega} + \frac{n}{R} \frac{\bar{\xi}}{\bar{q}} \frac{\bar{q}'(r)}{(k^2 + n^2/R^2 + m^2\gamma^2)} \quad [25]$$

Here, m is the vertical wave number, and

$$\gamma^2 = \frac{\bar{\eta}\bar{\xi}}{N^2} = \frac{I^2}{N^2} \quad [26]$$

where I is the inertial frequency, and N is the Brunt–Väisälä frequency of the azimuthal mean barotropic vortex.

The azimuthal phase speed of the waves can be written as

$$C_{p\lambda} = \frac{\omega}{n/R} = R\bar{\Omega} + \frac{\bar{\xi}}{\bar{q}} \frac{\bar{q}'(R)}{[k^2 + n^2/R^2 + m^2\gamma^2]} \quad [27]$$

The radial group velocity is

$$C_{gr} = \frac{\partial\omega}{\partial k} = -\frac{n}{R} \frac{\bar{\xi}}{\bar{q}} \frac{2k\bar{q}'(R)}{[k^2 + n^2/R^2 + m^2\gamma^2]^2} \quad [28]$$

Now the stagnation radius becomes

$$r_s = R + \frac{\bar{\xi}\bar{q}'}{\bar{q}R\bar{\Omega}'} \frac{1}{[k_0^2 + n^2/R^2 + m^2\gamma^2]} \quad [29]$$

These new formulae for baroclinic motion are very useful but caution needs to be paid to the condition in obtaining them. For example, this is a linear WKB solution. The basic state is assumed slowly varying in radial direction and barotropic in the vertical.

VRWs can be generated by various physical processes in hurricanes. In the lower troposphere, air parcels flowing inward and spiraling upward in the convective eyewall usually experience a material increase in PV. Since this material increase in PV can be especially rapid near the eyewall, an annular tower of high PV with low PV in the central eye region could be possible if there are no asymmetries in eyewall convection at the beginning, and if the material PV concentration could continue without any other processes to mix the PV into the eye region. Thus, barotropic instability near the eyewall can be expected. This type of instability can lead to eyewall breakdown and polygonal eyewall structure. When the instabilities grow to finite amplitude, the vorticity in the eyewall region pools into discrete areas, creating the appearance of polygonal eyewalls. The circulations associated with these vorticity pools exhibit a connection to mesovortices in the eyewall. At later times, the vorticity is redistributed into a nearly monopole circular vortex through eye contraction and PV mixing. In addition to barotropic instability, VRWs can be forced and driven by convective asymmetries in the eyewall. Such convective asymmetries in the eyewall can be generated by barotropic instabilities in the upper-tropospheric outflow layer, the beta effect, or environmental flow and flow shears (Wang and Wu, 2004). Neutral VRWs could also be present near the eyewall region where the radial PV gradients are large. Propagation of these forced or neutral waves along the eyewall can produce an apparent cyclonic rotation of the polygonal eyewall in some hurricanes (Kuo et al., 1999; Wang, 2002b).

The barotropic instability in the hurricane eyewall can be understood in the nondivergent barotropic model (Schubert

et al., 1999). The linearized nondivergent barotropic flow on an f -plane in cylindrical coordinates is governed by

$$\left(\frac{\partial}{\partial t} + \bar{\Omega} \frac{\partial}{\partial \lambda}\right) \nabla^2 \psi' - r \frac{\partial \psi'}{\partial \lambda} \frac{\partial \bar{\xi}}{\partial r} = 0 \quad [30]$$

where $\bar{\Omega}(r) = \frac{\bar{V}_\theta(r)}{r}$ is basic-state angular velocity and $\bar{\xi}(r) = \frac{d(r\bar{V}_\theta)}{rdr}$ is basic-state relative vorticity. Assuming a three-region distribution of vorticity

$$\bar{\xi}(r) = \begin{cases} \xi_1, & 0 \leq r \leq r_1 \\ \xi_1 + \xi_2, & r_1 < r \leq r_2 \\ 0, & r_2 < r < \infty \end{cases} \quad [31]$$

Search the solutions of the form

$$\psi'(r, \lambda, t) = \hat{\psi}(r) e^{i(m\lambda - \omega t)} \quad [32]$$

Substituting eqn [32] into eqn [30], and noting eqn [31] and if r does not cross the boundaries of the three regions, we have

$$r \frac{d}{dr} \left(r \frac{d\hat{\psi}}{dr} \right) - m^2 \hat{\psi} = 0, \quad \text{for } r \neq r_1, r_2 \quad [33]$$

Solutions of eqn [33] are first and second Bessel functions. Using the continuity conditions at r_1 and r_2 , finally we can obtain the growth rate formula

$$\frac{\nu}{\zeta_{ave}} = \frac{1}{4} \left\{ m + (m-1)\gamma \pm \left[\left(m - (m-1)\gamma - 2 \left(\frac{1-\gamma\delta^2}{1-\delta^2} \right)^2 + 4 \left(\frac{1-\gamma\delta^2}{1-\delta^2} \right) \left(\gamma - \frac{1-\gamma\delta^2}{1-\delta^2} \right) \delta^{2m} \right]^{1/2} \right\} \quad [34]$$

where $\delta = \frac{r_1}{r_2}$ is the ring thinness parameter ($\delta \rightarrow 1$ for very

thin rings), $\gamma = \frac{\xi_1}{\zeta_{ave}}$ is the hollowness parameter ($\gamma \rightarrow 0$ for very hollow rings), and ζ_{ave} is the average vorticity inside $r = r_2$

Figure 5 shows clearly the preference for higher wave numbers as the annular ring becomes thinner. Thinner annular regions would produce the highest growth rates but at much higher azimuthal wave numbers. Note that all basic states with $\gamma < 1$ satisfy the Rayleigh necessary condition for barotropic instability but that most of the region $\gamma < 1$, $\delta < 1/2$ is in fact stable. Note also the overlap in the unstable regions of γ - δ plane for different azimuthal wave numbers. For example, the lower-right area of the plane is unstable to all the azimuthal wave numbers $m = 3, 4, \dots, 8$.

The linear stability analysis is applicable to initial development of the instability to small perturbations. Once the amplitude of the disturbances increases exponentially with time initially, the subsequent evolution is nonlinear and involves wave breaking and PV mixing and pooling, appearance of mesovortices, merging and axisymmetrization, and eventually formation of monopole structure (Figure 6) or relatively stable discrete vortices (Figure 7). The appearance of wave breaking during the evolution toward a monopole vorticity distribution is hypothesized as one of the processes contributing to the polygonal eyewall structure in real hurricanes. The existence of the multiple mesovortices in the final stage of the nonlinear evolution as shown in Figure 7 can explain the formation of eyewall mesovortices in observations.

Figure 5 Isolines of the dimensionless growth rate, computed from eqn [34], as a function of δ and γ for azimuthal wave number $m = 3, 4, \dots, 8$. Positive growth rates occur only in the shaded regions. From Schubert, W.H., Montgomery, M.T., Taft, R.K., Guinn, T.A., Fulton, S.R., Kossin, J.P., Edwards, J.P., 1999. Polygonal eyewalls, asymmetric eye contraction, and potential vorticity mixing in hurricanes. *Journal of Atmospheric Sciences* 56, 1197–1223.

Figure 7 Vorticity contour plots for the representative nonlinear evolution of an annular vorticity ring involving into discrete mesovortices. Note that the initially most unstable wave number of the asymmetries follows the prediction by the linear stability (Taft, R.K., Schubert, W.H, 2013).

In addition to the internal dynamical instability, vertical shear of horizontal wind is considered to be one of the major environmental forcings that can cause robust asymmetric structure in hurricanes (e.g., Reasor et al., 2000; Black et al., 2002). The vertical shear-induced convective asymmetry in the inner core region is considered to be negative to hurricane intensification and maximum potential intensity (MPI). The development of convective asymmetries in the inner core region of a hurricane embedded in a vertically sheared environmental flow is often attributed to the relative flow across the elevated cyclonic vorticity or PV core (Wang and Holland, 1996a; Frank and Ritchie, 2001; Black et al., 2002; Zhang and Kieu, 2005). Both observations and numerical simulations show enhanced upward motion and convection downshear left of the hurricane center and suppressed upshear right when facing downshear (Figure 8).

Vertical wind shear can often cause the vertical tilt of the hurricane vortex. However, strong hurricanes can still maintain entity in weak and moderate vertical wind shear. This vertical alignment can be understood as an initially barotropic vortex embedded in a vertical shear on an f -plane (Figure 9). A vertically tilted vortex can be considered to consist of a core of positive vorticity surrounded by a skirt of lesser positive vorticity align through projection of the tilt asymmetry onto VRWs and their subsequent damping (Reasor et al., 2004). The VRW damping mechanism provides

a direct means of reducing the tilt of intense hurricane vortices in unidirectional vertical shear (Figure 9). For initially upright, hurricane-like vortices in vertical shear, a ‘downshear-left’ tilt equilibrium is achieved when the VRW damping is effective. Therefore, the inviscid damping mechanism intrinsic to the dry adiabatic dynamics of a hurricane vortex can suppress departure from the upright state of a strong hurricane. Figure 10 shows examples of the evolution of two vortices embedded in a westerly shear. For a broad vortex that has vorticity skirt, the VRW damping mechanism is quite effective and results in a quasi-left tilt to the vertical shear (Figure 10(a)). For a narrow vortex with little vorticity skirt, an oscillation between the upper- and lower-level centers occurs (Figure 10(b)). Therefore, the vertical alignment of a hurricane-like vortex in vertical shear is sensitive to the structure of the hurricane vortex itself. Nevertheless, if the vertical shear is too strong, the alignment would be impossible and an up-down weakening of the hurricane vortex will occur even though the moist processes are included (Frank and Ritchie, 2001; Xu and Wang, 2013).

Concentric Eyewall Cycles

In some strong hurricanes, some of the outer rainbands may strengthen and organize into a ring of convection, named an outer eyewall or a secondary eyewall, that slowly moves inward

Figure 8 Schematic illustration of the shear-induced convective asymmetry based upon observations of Hurricanes Jimena and Olivia. The low-level environmental flow is indicated by the two solid black arrows. Upper-level flow is indicated by the three stippled arrows. Convective cells form somewhat upwind of the downshear side of the eyewall. They advect around the eye into the semicircle to the left of the shear vector where warm rain processes generate hydrometeors large enough to reflect radar effectively. Precipitation-driven downdrafts begin about 90° to the left of the shear vector. By the time, the cells reach the upshear side of the eyewall they have ascended through the 0 °C isotherm and downdrafts predominate below 6 km. As the cells move into the semicircle on the right of the shear vector, most condensate freezes or falls out of the active updrafts. The unloaded updrafts accelerate upward. They detach themselves from the eyewall and approach the tropopause as they rotate through the semicircle to the right of the shear. From Black, M.L., Gamache, J., Dodge, P., Barnes, G., Marks, F., Hudson, J., Castells, T., 2002. Eastern Pacific Hurricanes Jimena of 1991 and Olivia of 1994: the effect of vertical shear on structure and intensity. *Monthly Weather Review* 130, 2291–2312.

and robs the original eyewall or the inner eyewall of its needed moisture and angular momentum. This usually causes the weakening of the inner eyewall and the storm during this phase. Eventually, the outer eyewall replaces the inner one and the storm may re-intensify (an example is shown in [Figure 11](#) for Hurricane Ivan (2004), [Terwey and Montgomery, 2008](#)). As such, the development of a concentric eyewall and the subsequent eyewall replacement (or the concentric eyewall cycle) are one of the major mechanisms that often result in rapid hurricane structure and intensity changes ([Willoughby et al., 1982](#); [Houze et al., 2007](#); [Stikowski et al., 2012](#); [Kossin and Stikowski, 2012](#)).

Although the concentric eyewall cycle is important to hurricane structure and intensity changes, there have been no any complete theories that can explain all aspects of the concentric eyewall cycle so far. Several hypotheses have been proposed to explain the dynamics of the secondary (concentric) eyewall formation (SEF). Axisymmetrization of spiral rainbands is considered to be a plausible process causing the SEF ([Willoughby et al., 1982](#); [Black and Willoughby, 1992](#); [Kuo et al., 2004, 2008](#); [Wang, 2009](#); [Judt and Chen, 2010](#)). Since the spiral rainbands can be triggered by either internal dynamics or external forcing, the rainband axisymmetrization mechanism suggests that the SEF could be either an internal process or triggered by external forcing or their combination. For example,

the eddy angular momentum flux associated with an upper-tropospheric trough may initiate deep convection outside the eyewall and trigger major outer spiral rainbands and the SEF ([Molinari and Vollaro, 1990](#); [Nong and Emanuel, 2003](#); [Zhu et al., 2004](#)). Spiral rainbands can also be triggered by internal dynamics, such as VRWs, convective instability outside the eyewall, and frictional boundary layer dynamics. These are proposed to explain the dynamics of the SEF or part of the concentric eyewall cycle.

Although the secondary eyewall involves moist processes, the dynamics of its initiation has also been explained by dry adiabatic processes. The first mechanism is that associated with the activity of VRWs. The stagnation radius of outward energy dispersion of VRWs is suggested to be an ideal location for strongest wave-mean flow interaction and could trigger the formation of a local (secondary) wind maximum, which can supposedly enhance the surface heat and moist flux, helps to initiate a ring of convection, and thus the SEF ([Montgomery and Kallenbach, 1997](#); [Qiu et al., 2010](#); [Abarca and Corbosiero, 2011](#); [Martinez et al., 2011](#)).

The second mechanism is the so-called beta skirt axisymmetrization (BSA) mechanism ([Terwey and Montgomery, 2008](#)) that describes an upscale cascade of EKE in the presence of the differential rotation associated with the radial gradient of the azimuthal mean vorticity (beta skirt). By the BSA

Figure 9 Schematic of the tropical cyclone alignment mechanism when the tropical cyclone is tilted by vertical shear. (a) The primary tropical cyclone circulation (into and out of the page) is maintained in the presence of frictional drag through stretching of mean tropical cyclone vorticity by the diabatically driven axisymmetric secondary circulation. (b) Vertical shear causes the tropical cyclone to tilt (with vertical tilt angle α). Eyewall convection responds by becoming increasingly asymmetric, with a maximum in the downshear quadrant of the storm. The asymmetric component of convection increases at the expense of the symmetric component shown in (a). No longer able to offset the frictional drag, the mean tropical cyclone weakens. In the absence of an intrinsic mechanism to realism, the tropical cyclone will shear apart. (c) Recent work has identified an intrinsic alignment mechanism called vortex Rossby wave (VRW) damping. VRW damping counters differential advection of the tropical cyclone by the vertical shear flow. (d) For sufficiently strong VRW damping, a quasi-aligned vortex is possible with a secondary circulation similar to the axisymmetric configuration of (a). From Reasor, P.D., Montgomery M.T., Grasso, L.D., 2004. A new look at the problem of tropical cyclones in vertical shear flow: vortex resiliency. *Journal of Atmospheric Sciences* 61, 3–22.

mechanism, in a region with a substantial overlap between the beta skirt and an area of strong convective potential outside the eyewall, cumulus convective activity acts as a source of eddy vorticity and aids in the formation of a low-level jet by forcing additional low-level inflow into a narrow annular region. Upon coupling with the boundary layer via surface enthalpy flux, the induced jet can then amplify and enforce additional cumulus convection. This positive feedback and the continuous axisymmetrization lead to the SEF.

Different from the wave-mean flow and the eddy-mean flow interaction mechanisms that focus on asymmetric processes and the subsequent axisymmetrization for the SEF, the third

mechanism is an axisymmetric view associated with the forcing in the inflow boundary layer (Wu et al., 2012; Huang et al., 2012; Bell et al., 2012; Wang et al., 2013; Abarca and Montgomery, 2013; Kepert, 2013). By this mechanism, the SEF is described as a sequence of structure changes in the outer core region starting from the broadening of the tangential winds above the inflow boundary layer. This is followed by an increase of the radial inflow in the boundary layer and super-gradient winds in and just above the boundary layer, leading to an enhancement of convergence in the boundary layer where convective ring is triggered and the secondary eyewall forms. The activity of spiral rainbands contributes to the broadening

Figure 10 Schematic illustration of the vortex tilt evolution for the case where (a) the vortex Rossby wave (VRW) damping rate is a nonnegligible fraction of the precession frequency and (b) the VRW damping rate is zero. The initially aligned vortex is tilted by westerly vertical shear. The vortex center at upper levels is denoted by the stars and at lower levels by the hurricane symbols. The thin arrows indicate the direction of motion of the upper- and lower-level centers. The vortex in (a) achieves a steady-state tilt to the left of the vertical shear vector. In (b) the vortex tilts downshear, precesses cyclonically upshear, realigns, and then repeats this evolution. From Reasor, P.D., Montgomery M.T., Grasso, L.D., 2004. A new look at the problem of tropical cyclones in vertical shear flow: vortex resiliency. *Journal of Atmospheric Sciences* 61, 3–22.

of tangential wind above the boundary layer (Fudeyasu and Wang, 2011; Rozoff et al., 2012; Sun et al., 2013) and the hurricane wind structure determines the radial location of the boundary layer convergence and thus convective ring and the SEF (Abarca and Montgomery, 2013; Kepert, 2013). Note that diabatic heating in the stratiform precipitation region in spiral rainbands plays much more important role in the broadening and thus the SEF (Moon and Nolan, 2010; Moon et al., 2010; Fudeyasu and Wang, 2011).

In summary, the SEF is initially triggered by active spiral rainbands, in particular outer spiral rainbands. These rainbands play two important roles. On one hand, the balance response to diabatic heating in spiral rainbands is a broadening of tangential wind in the mid-lower troposphere above the boundary layer (Fudeyasu and Wang, 2011; Rozoff et al., 2012). On the other hand, outer spiral rainbands act as a barrier to the boundary layer inflow and produce downdrafts in the inflow boundary layer inside the rainbands, both suppressing eyewall convection (Wang, 2009) and terminating the intensification of the hurricane or weakening the hurricane. The reduction of diabatic heating associated with eyewall convection would reduce the boundary layer inflow into the eyewall, also favoring the broadening or outward expansion of tangential wind. The increase of the radial inflow in the boundary layer and the associated supergradient winds in and just above the boundary layer leads to an enhanced convergence in the boundary layer where the spiral rainbands are axisymmetrized to form a convective ring, leading to the SEF (Sun et al., 2013). Since the SEF is preconditioned by active spiral rainbands, any weak asymmetric forcing may be helpful for the SEF. These asymmetric forcings may be beta effect (Wang, 2006; Fang and Zhang, 2012), weak vertical wind shear (Zhu et al., 2004), and the upper-tropospheric trough (Molinari and Vollaro, 1990; Nong and Emanuel, 2003).

Dynamics of Genesis

A fundamental concept in understanding the atmospheric phenomena in the tropics is the so-called scale interaction that describes the positive/negative feedback processes among circulations at different time and spatial scales. In particular, cumulus convection and its synoptic-scale environmental flow are generally interacting in some cooperative ways. Some of these interactions are proposed to explain hurricane genesis. One of these feedbacks is the so-called conditional instability of the second kind (CISK) that describes the cooperative development of an existing synoptic-scale disturbance and the embedded convection (Charney and Eliassen, 1964; Ooyama, 1964, 1969). In this viewpoint, diabatic heating due to latent heat released by cumulus clouds enhances a preexisting synoptic cyclonic disturbance; this disturbance, in turn, through boundary layer pumping in the presence of surface friction, drives the low-level moisture convergence necessary to maintain an environment favorable for the development of cumulus convection. Since the boundary layer friction and Ekman pumping play a central role in enhancing the large-scale moisture convergence, this feedback is termed Ekman-CISK. This positive feedback can be schematically illustrated in Figure 12. In addition to the Ekman-CISK, moist convection can be organized and enhanced by waves in the tropics as well. In this case, upward motion and large-scale moisture convergence in the wave trough may trigger deep convection; latent heating due to cumulus convection in turn can then amplify the wave, and thus a positive feedback. This positive feedback is termed wave-CISK. Both Ekman-CISK and wave-CISK are frequently used to explain the development of synoptic-scale disturbances in the tropics, including the genesis and intensification of hurricanes. The CISK needs the conditionally unstable conditions in the large-scale

Figure 11 (a) Best track sea surface pressure trace from the National Hurricane Center for Hurricane Ivan (2004). (b) Research aircraft radar reflectivity composite of Ivan with two eyewalls. At this time, the central pressure is about to begin increasing, indicating a temporary decrease in the intensity of the storm correlated with the secondary eyewall cycle. Terwey, W.D., Montgomery, M.T., 2008. Secondary eyewall formation in two idealized, full-physics modeled hurricanes. *Journal of Geophysical Research* 113, D12112. <http://dx.doi.org/10.1029/2007JD008897>.

environment and convection is considered as an internal heating source with fundamental forcing from boundary layer moisture convergence.

Another distinct view of hurricane genesis is the air-sea interaction that describes the feedback between the surface cyclonic winds in the inner core of a prehurricane synoptic disturbance and the wind-induced surface heat exchange (WISHE). According to this viewpoint, the potential energy for the synoptic disturbance arises from the thermodynamic disequilibrium between the atmosphere and the underlying ocean (Emanuel, 1986, 2003). The efficacy of air-sea

interaction in providing potential energy to balance frictional dissipation depends on the rate of transfer of latent heat from the ocean to the atmosphere. This is a function of surface wind speed; strong winds, which produce a rough sea surface, can increase the ocean surface evaporation. Thus the system development depends on the presence of a finite-amplitude preexisting synoptic disturbance to provide the winds required to produce strong evaporation. Given a suitable initial disturbance, a feedback may occur in which an increase in inward spiraling surface winds increases moisture flux from the ocean, which by bringing the boundary layer toward saturation

Figure 12 Schematic of a positive feedback between moist convection and synoptic-scale disturbance as described in the Ekman-CISK paradigm of hurricane genesis. Frictionally induced boundary layer convergence moistens the synoptic disturbance and destabilizes it through Ekman pumping and layer ascent. This enables small-scale plumes to reach their levels of free convection easily and to produce cumulonimbus clouds. Diabatic heating due to the resulting precipitation lowers the low-pressure system and drives the large-scale circulation and thus maintains/enhances the large-scale convergence.

increases boundary layer equivalent potential temperature (θ_e) and enhances convection. Convection plays a role in redistributing θ_e vertically along the outwardly tilted AAM surface near the RMW. This vertical redistribution of θ_e lowers the central pressure and increases radial pressure gradient and the surface wind and thus surface heat flux and boundary layer θ_e again – a positive feedback (Figure 13). WISHE theory is widely accepted to explain both genesis and the subsequent intensification of hurricanes and is better supported by observations.

Both CISK and WISHE emphasize the cooperative intensification of storm scale circulation and either cumulus convection or WISHE near the RMW under the eyewall. However, observations show the importance of extremely strong swirling convective cores, which are termed vortical hot towers (VHTs), in hurricane genesis. The VHT route to hurricane genesis describes an upscale organization process (Hendricks et al., 2004; Montgomery et al., 2006). VHTs are referred to cumulonimbus towers possessing preferred coherent structures with intense cyclonic vorticity in their cores. VHTs acquire their vertical vorticity through a combination of tilting of

Figure 13 Schematic of a positive feedback between surface enthalpy flux and winds in a preexisting synoptic-scale disturbance as described in the WISHE paradigm of hurricane genesis. Surface heat exchange increases boundary layer θ_e , high θ_e is redistributed vertically in the outwardly tilted eyewall along the AAM near the radius of maximum wind (RMW), lowers the central pressure and increases the pressure gradient across the RMW and thus surface wind, which in turn increases the surface heat exchange.

horizontal vorticity, stretching, and diabatic heating. VHTs often have convective lifetimes in the order of an hour or so. They can overcome the adverse effect of downdrafts by consuming convective potential energy in their local environment, humidifying the mid-upper troposphere, and undergoing diabatic vortex merger with neighboring towers to increase both the strength and size of the initial mesoscale convective vortex (MCV). A quasi-balanced transverse circulation develops on the storm scale as a response to the collective diabatic heating from the ensemble or aggregate of VHTs. The forced low-level inflow can pool cyclonic vorticity of the initial MCV and small-scale vorticity anomalies generated by subsequent VHTs. This can accelerate the spinup of near-surface mean tangential winds and serves as an upscale growth mechanism for the development of a preexisting synoptic disturbance on timescales in the order of 1–2 days. In addition, VHTs themselves can be agents to largely enhance the surface entropy flux and thus the energy gain from the ocean for the parent MCV. Since WISHE describes the positive feedback between system-scale surface winds and surface entropy flux, the VHT route thus does not critically depend on the WISHE mechanism.

The VHT route above can be generalized to take into account multiscale vortices or given a term ‘multiscale vortex route’ to hurricane genesis (Sippel et al., 2006; Fudeyasu et al., 2010; Fang and Zhang, 2010, 2011). By multiscale vortex route, various scale vortices might coexist in a system-scale vortex (the preexisting synoptic-scale disturbance or an embedded incipient synoptic vortex), including MCVs (meso- α , - β , - γ scale), VHTs, and also convective bursts and convective cells or cloud clusters. Most of these vortices are vorticity-rich and show apparent self-similarities in their structures and behaviors. Each of these vortices may undergo several cycles before it merged or aggregated with its stronger neighbor. The vorticity and energy produced by these individual vorticity-rich convective vortices first saturate at convective scales that are then transferred to larger scales. As in the VHT route, the ensemble of diabatic heating released from these convective vortices acts as a persistent forcing to the quasi-balanced system-scale vortex and drives the transverse secondary circulation. The system-scale secondary circulation converges the cluster- and convective-scale vorticity anomalies into the core region of the system-scale vortex. As a result, convergence and projections of the smaller-scale vorticity to the larger scales eventually lead to the spinup of the system-scale vortex and thus the hurricane genesis (Figure 14).

Another paradigm of hurricane genesis is the so-called marsupial paradigm that emphasizes the importance of the critical layer of a tropical easterly wave to hurricane formation (Dunkerton et al., 2009; Wang et al., 2010). The theory is based on the following three hypotheses: (1) Wave breaking or roll-up of the cyclonic vorticity near the critical surface in the lower-troposphere provides a favored region for the aggregation of vorticity seedlings and TC formation; (2) The wave critical layer is a region of closed circulation, where air is repeatedly moistened by convection and protected from dry air intrusion; (3) The parent wave is maintained and possibly enhanced by diabatically amplified mesoscale vortices within the wave. Genesis tends to occur near the intersection of the critical surface and the trough axis of the precursor parent wave,

Figure 14 Evolution of the vorticity anomalies at $z = 188$ m centered on the incipient Hurricane Dolly (2006) every 3 h from 1200 UTC 21 to 2100 UTC 22 July 2006 in a cloud-resolving simulation. Color shadings represent vorticity of the anomalies with the horizontal scales larger than 50 km but smaller than 150 km. Contours represent vorticity of the anomalies with the horizontal scales larger than 150 km (every $1.5 \times 10^{-4} \text{ s}^{-1}$) and axes are in kilometers. Note that all vorticity anomalies with horizontal scales less than 50 km have not been shown for clarity. From Fang, J., Zhang, F., 2010. Initial development and genesis of Hurricane Dolly (2008). *Journal of Atmospheric Sciences* 67, 655–672.

which is the center of the pouch (see **Tropical Cyclones and Hurricanes: Tropical Cyclogenesis** for more details about this paradigm). The marsupial paradigm thus emphasizes the roles of the preexisting synoptic disturbance and the subsequent mesoscale and convective-scale processes in hurricane genesis.

Hurricane genesis is a highly nonlinear process and should be considered as a finite-amplitude amplification process (Ooyama, 1982; Emanuel, 1989). The ability of the initial convection to survive for several days and to interact with the synoptic disturbance depends on the Rossby radius of deformation that is defined as

$$L_R = \frac{NH}{f} \quad [35]$$

where N is the Brunt–Vaisala frequency, H is the scale height, and f is the Coriolis parameter. The Rossby radius of deformation is the length scale at which rotational effect becomes as important as gravity wave effect in the evolution of the flow in a disturbance. L_R is inversely proportional to latitude so it is very large in the tropics. However, in a finite-amplitude disturbance with considerable vorticity (e.g., a circular vortex or a hurricane), the Rossby radius of deformation can be largely reduced locally. In this case, the Coriolis parameter will be replaced by the inertial stability parameter and the local Rossby radius of deformation becomes

$$L_R = \frac{NH}{I} \quad [36]$$

The small local Rossby radius of deformation makes the convective heating locally to allow the low-pressure system to develop. Both CISK and WISHE require a preexisting synoptic-scale disturbance. This disturbance needs to be finite-amplitude to allow the feedback to occur. Furthermore, although we have several mechanisms that may explain the genesis processes, their relative importance is still hard to measure because of the nonlinear nature of the processes. Nevertheless, these mechanisms may function cooperatively in hurricane genesis.

Dynamics of Intensification

In the dynamics of genesis, both CISK and WISHE may explain the intensification of hurricanes as well. The dynamics of intensification of a hurricane can be further understood based on the balanced dynamics. The transverse circulation in an axisymmetric hurricane vortex, which is in both the gradient wind and hydrostatic balances, can be described using the Sawyer–Eliassen equation in balanced dynamics (Shapiro and Willoughby, 1982)

$$\frac{\partial}{\partial r} \left(\frac{A}{r\rho_0} \frac{\partial \psi}{\partial r} + \frac{B}{r\rho_0} \frac{\partial \psi}{\partial z} \right) + \frac{\partial}{\partial z} \left(\frac{C}{r\rho_0} \frac{\partial \psi}{\partial z} + \frac{B}{r\rho_0} \frac{\partial \psi}{\partial r} \right) = -\frac{\partial(\xi F_v)}{\partial z} + \frac{g}{C_p T_0} \frac{\partial Q}{\partial r} \quad [37]$$

where A , B , and C are, respectively, static stability, baroclinity, and inertial stability, and are given by $A = N^2$, $B = -\xi S = -\left(f_0 + \frac{2V_T}{r}\right) \frac{\partial V_T}{\partial z} = -\frac{g}{\theta_0} \frac{\partial \theta}{\partial r}$, and $C = \xi \eta = \left(f_0 + \frac{2V_T}{r}\right) \left(f_0 + \frac{1}{r} \frac{\partial r V_T}{\partial r}\right) = I^2$. Given the structure of the vortex, thus A , B , and C , and the distribution of heating (Q) and momentum (F_v) sources, solution of this generalized Poisson equation yields the secondary circulation when the elliptic condition $AC - B^2 > 0$ is satisfied everywhere in the vortex and proper boundary conditions are specified. The natural boundary conditions for eqn [37] are ψ vanishes at $r = 0$ and $z = 0, z_T$, and $r\psi \rightarrow 0$ as $r \rightarrow \infty$, where z_T is the top of the vortex, such as the tropopause. The above balance relation can be used to deduce the secondary (transverse) circulation from the distribution of heat and momentum sources given the axisymmetric structure of the basic hurricane vortex. Since the mass is nondivergent in the r - z plane, it may be represented with the mass streamfunction such that

$$V_r = -\frac{1}{r\rho_0} \frac{\partial \psi}{\partial z}, \quad w = \frac{1}{r\rho_0} \frac{\partial \psi}{\partial r} \quad [38]$$

Since the right-hand side of eqn [37] contains derivatives of momentum and heat sources with respect to z and r , respectively, the streamfunction field due to an isolated patch of forcing would be a dipole, namely, two adjacent counter-rotating elliptical gyres with flow between them passing through the source. For a heat source, the dipole axis that joins the foci of the ellipses is nearly horizontal. An updraft passes through the source following a (nearly vertical) surface of constant angular momentum and is flanked by compensating descent on both sides (Figure 15(a)). For a cyclonic momentum source, the dipole axis is nearly vertical with radial outflow passing through the source following an (nearly horizontal) isentropic surface and compensating inflow above and below (Figure 15(b)).

Figure 15 Secondary circulation induced in a balanced warm-core vortex by (a) a heat source and (b) a cyclonic momentum source, showing the distortion induced by variation in inertial stability I^2 , thermodynamic stability N^2 , and baroclinity B . The strong motions through the source follow lines of constant angular momentum for a heat source and of constant potential temperature for a momentum source. From Willoughby, H.E., 1995. Mature structure and evolution. In: Elsberry, R.L. (Ed.), *Global Perspectives of Tropical Cyclones*. pp. 21–62. WMO/TD-No 693. World Meteorological Organization, Geneva, 289pp.

Substitution of V_r and w into tangential momentum equation and thermodynamic equation allows calculation of $\partial V_T/\partial t$ and $\partial \theta/\partial t$ to march the solution forward in a prognostic model below

$$\frac{\partial V_T}{\partial t} + V_r \zeta_a + w \frac{\partial V_T}{\partial z} = F_v \quad [39]$$

$$\frac{g}{\theta_0} \frac{\partial \theta}{\partial t} + \frac{g}{\theta_0} V_r \frac{\partial \theta}{\partial r} + N^2 w = \frac{gQ}{C_p T_0} \quad [40]$$

where $\zeta_a = f + \frac{\partial r V_T}{\partial r}$ is the absolute vorticity. We can get the evolution of the balanced vortex provided the heat and momentum sources. Since θ is connected to pressure field through hydrostatic equation, once we get the solution for the secondary circulation (V_r, w) through the streamfunction given either heat or momentum source or both, we can readily get the tendencies of pressure and tangential wind speed. This can be used as a diagnostic approach to understand the intensification dynamics of hurricanes.

Figure 16 gives examples for the response of surface tangential wind to a specified mid-tropospheric heating source (left) and a cyclonic momentum source (right) in a balanced barotropic hurricane-like vortex. In this case, heating source centered at the RMW ($r^* = 1$) spins down the tangential winds in the eye region but spins up tangential winds near and outside the RMW (left in Figure 16). In contrast, any cyclonic momentum source imposed in the mid-troposphere near the RMW would spin up the tangential winds mainly within the RMW (right in Figure 16). In both cases, the increase in tangential winds is the maximum inside the RMW, indicating a contraction of the RMW and an intensification of the storm.

The response is sensitive to the radial position of the sources and is the strongest when the sources are slightly inside of the RMW but becomes weaker when the sources are located far away from the RMW. For the lower-tropospheric heat or momentum source at somewhat larger radius, negative tangential wind tendencies would be induced near the center or even beyond the RMW. This mechanism may explain how outer concentric eyewalls replace a preexisting inner eyewall. This may also explain the increase in storm inner-core size in

Figure 16 Responses of the transverse circulation (upper panels) and tangential wind at the surface (lower panels) to the mid-tropospheric heat (left) and cyclonic momentum (right) sources at the RMW in a balance barotropic vortex. From Shapiro, L.J., Willoughby, H.E., 1982. The response of balanced hurricanes to local sources of heat and momentum. *Journal of Atmospheric Sciences* 39, 378–394.

real hurricanes. Although the details in a baroclinic vortex could be different, the response is qualitatively similar to those shown in Figure 16 in a barotropic vortex.

The response efficiency to heat and momentum sources also depends on the intensity of the vortex itself (Figure 17). It is clear that the surface wind tendency response to heat source near the RMW increases with the intensity of the balanced vortex or equivalently with the decrease in the Rossby radius of deformation that is inversely proportional to the inertial stability. This is mainly because the heating efficiency depends on the inertial stability in the neighborhood of the heat source. As we can see from Figure 18, the warming in the inner core region of a hurricane vortex in response to heating in the eyewall is proportional to the inertial stability. This is consistent with the surface tangential tendency response to heat source. For a fixed heating rate, the surface wind tendency is greatest for heating inside the eye in vortices having the largest vorticity just inside the RMW; whereas the greatest tendency occurs for heating outside the eye for vortices with the largest vorticity outside the RMW (Pendergrass and Willoughby, 2009; Vigh and Schubert, 2009).

Since the inertial stability is a function of the maximum tangential wind speed and the RMW and in general the maximum tangential wind increases and the RMW decreases in intensifying hurricane vortex, the intensification rate for fixed heating thus would increase with increasing intensity if the vortex shape remains the same. This implies a positive feedback during intensification of a hurricane. Eyewall heating causes strengthening of the primary vortex and contraction of the eye that make further intensification more efficient. In nature,

however, as a hurricane intensifies to approach its MPI, the role of heating will be balanced by the effect of surface frictional dissipation, causing the intensity to asymptote to the MPI despite greater efficiency.

The above insights into the dynamics of hurricane intensification are gained based on balanced dynamics. The unbalanced dynamics due to the presence of the frictional boundary layer also plays important roles in hurricane intensification. On the one hand, surface friction is negative to the boundary layer tangential wind tendency. On the other hand, it reduces the tangential wind speed and thus the centrifugal force, largely enhancing the boundary layer inflow and thus the inward transport of AAM and positive to the tangential wind tendency. As a result, the net effect of surface friction to hurricane intensification depends on the magnitudes of the two contributions to the tangential wind tendency. If the radial pressure gradient, thus the gradient wind, above the boundary layer is determined by the eyewall heating, the boundary layer inflow enhanced by surface friction can dominantly increase the tangential wind tendency in the inner core region of a hurricane vortex where the absolute vorticity is elevated (see eqn [39]). This process is often used to explain the presence of the supergradient wind in the upper part of the inflow boundary layer under the eyewall and a low-level jet near the top of the inflow boundary layer in the inner core region (Kepert, 2001; Kepert and Wang, 2001; Smith, 2003; Smith and Montgomery, 2010). This is also considered a second mechanism for the inner core spinup of an intensifying hurricane vortex (Bui et al., 2009; Smith et al., 2009).

Surface friction also significantly enhances the inward penetration of boundary layer inflow into the eye region and leads to the maximum in eyewall updrafts slightly insight the RMW at the top of the boundary layer (Wang and Wang, 2014), thus increasing the heating efficiency as discussed above. On the other hand, this inward penetration also contributes to the contraction of the eyewall in addition to the formation of supergradient wind and low-level jet near the top of the inflow boundary layer in the inner core region. Therefore, surface friction is important to the spinup of the inner core and

intensification and intensity of hurricanes (Bui et al., 2009; Smith et al., 2009; Smith and Montgomery, 2010).

In addition to the axisymmetric dynamics, hurricane genesis and intensification also involve asymmetric dynamics (Nolan and Farrell, 1999; Nolan et al., 2007). This should be more realistic but the asymmetric dynamics is neither necessary nor sufficient for hurricane genesis and intensification. Actually, the asymmetries in the inner core region of a hurricane vortex may play different roles in the different stage of the development of the hurricane (Möller and Montgomery, 2000; Wu and Braun, 2004; Yang et al., 2007; Persing et al., 2013). It seems that asymmetries in the core could contribute positively to the genesis and early intensification but negatively to the subsequent RI and the final maximum intensity.

Dynamics of MPI

A hurricane can be viewed as a Carnot heat engine with its energy cycle schematically shown in Figure 19 (Emanuel, 1986, 1991). The classical Carnot cycle in thermodynamics can be summarized based on the four legs. Leg 1 represents the isothermal expansion, namely gas is been heated and pressure is reduced, namely θ_e increases. Leg 2 represents an adiabatic expansion where there is no heat exchange and thus pressure is reduced but temperature is decreasing, keeping θ_e constant. Leg 3 represents an isothermal compression where gas is cooled, with pressure increased and thus θ_e decreases. Leg 4 represents an adiabatic compression where there is no heat exchange and pressure is increased while θ_e keeps constant. The mechanical work from the Carnot engine can be determined by

$$W = Q \left(\frac{SST - T_{out}}{SST} \right) \quad [41]$$

Figure 19 Schematic of the hurricane viewed as a Carnot engine of the classical Carnot cycle in thermodynamics. Leg 1 represents the isothermal expansion, namely gas is been heated and pressure is reduced, namely θ_e increases. Leg 2 represents an adiabatic expansion where there is no heat exchange and thus pressure is reduced but temperature is decreasing, keeping θ_e constant. Leg 3 represents an isothermal compression where gas is cooled, with pressure increased and thus θ_e decreases. Leg 4 represents an adiabatic compression where there is no heat exchange and pressure is increased while θ_e keeps constant. From Emanuel, K.A., 1991. The theory of hurricanes. *Annual Review of Fluid Mechanics* 23, 179–196.

where Q is the heat energy input from leg 1 and $\varepsilon = \frac{SST - T_{out}}{SST}$ is the thermodynamic efficiency of the heat engine, where SST is sea surface temperature and T_{out} is the temperature in the outflow layer.

For the hurricane case, the energy imports from the underlying ocean and exports in the outflow layer, giving the efficiency of the heat engine, and system loses mechanical energy to the surface due to friction (Emanuel, 1997). The net energy input gained for mechanical work thus can be written as

$$\text{Energy}_{\text{input}} = \int \varepsilon C_k \rho |\vec{V}| (k_o^* - k_a) r dr \quad [42]$$

where C_k is the enthalpy transfer coefficient at the surface, k_o^* is the saturation enthalpy at the SST, k_a is the enthalpy of the air in the well-mixed boundary layer,

$$k = [C_p(1 - q_v) + C_l q_v] T + L_v q \quad [43]$$

C_p and C_l are the heat capacities of dry air at constant pressure and of liquid water, respectively; $\vec{V}$ is the total near-surface wind speed, and ρ is the air density.

The mechanical energy loss to the underlying ocean from the system can be expressed as

$$\text{Dissipation} = \int C_D \rho |\vec{V}|^3 r dr \quad [44]$$

The changes of dissipation and energy input with wind speed are schematically given in Figure 20. We can see that the energy input increases with wind speed linearly while the dissipation increases with the cube of wind speed. The point where the two curves meet is the MPI the hurricane can achieve. Since the balance is mainly dominated by the winds under the eyewall, the balance can be assumed near the RMW. As a result, the MPI can be approximated by

$$V_m = \sqrt{\frac{C_k}{C_D} \varepsilon (k_o^* - k_a)} \quad [45]$$

Note that the dissipative heating due to surface friction is not included in eqns [42] and [45]. With dissipative heating considered, the factor SST/T_{out} should be multiplied to the right-hand side of eqn [42]. Therefore, compared with the result without the dissipative heating, the effect of including dissipative heating is identical to that of increasing the ratio of

surface exchange coefficient, C_k/C_d , by the factor SST/T_{out} . In hurricane environments, $SST/T_{out} \approx 3/2$, so including dissipative heating is equivalent to increasing the enthalpy transfer coefficient by 50% or to increasing the MPI by 22% (Bister and Emanuel, 1998).

The theoretical MPI discussed above considers the processes under the eyewall with a passive eye. However, the lower surface pressure in the eye provides a potential source of higher entropy air, which could be entrained into the eyewall, increasing the eyewall entropy and thus the MPI. This is proposed to explain the superintensity phenomenon in both observed and numerically simulated hurricanes whose intensity exceeds the MPI (Persing and Montgomery, 2003). It is suggested that the introduction of heat from the eye could lead to a modified Carnot cycle that allows for a stronger storm than that calculated from eqn [45]. The superintensity concept challenges the existing MPI theory. Nevertheless, the explanation by the excess energy in the eye region is found not to be sufficient since some studies indicate that the removal of high entropy anomaly in the eye only results in a reduction of about 4% in the maximum tangential wind speed, far too small to explain over 50% of the maximum tangential wind speed in observations and numerical simulations. Indeed, entropy budget analysis indicates that only less than 3% of the total entropy input to the TC comes from the eye region because of the small volume of the eye. As a result, the total magnitude of entropy transport from the eye to the eyewall is negligible to the entropy budget and the intensity of the hurricane in general (Bryan and Rotunno, 2009a).

The superintensity can be plausibly explained by energy input from outside of the eyewall region as later demonstrated in a numerical study, which shows that the surface frictional dissipation rate is about 25% higher than the energy production rate near the RMW (Wang and Xu, 2010). This indicates that the local balance hypothesis used to obtain eqn [45] would underestimate the maximum intensity of a hurricane. In contrast, the surface frictional dissipation rate is much lower than the energy production rate outside the eyewall. This implies that the excess frictional dissipation under the eyewall should be partially balanced by the energy production outside the eyewall. It is found that the energy production within about 2–2.5 times of the RMW outside the eyewall is also critical to the maximum intensity of a hurricane. This nonlocal effect is mainly accomplished by the unbalanced flow in the inflow boundary layer (Smith et al., 2008; Smith and Montgomery, 2010; Bryan and Rotunno, 2009b). Nevertheless, a complete theory including this closed energy budget for the MPI of a hurricane is yet to be developed.

Dynamics of Hurricane Motion

The motion of a hurricane is mainly controlled by the deep-layer mean environmental flow, or simply the steering flow. However, a hurricane often moves with considerable deviation from the steering flow. This deviation from the steering flow results mainly from the interaction between the hurricane vortex and the earth's vorticity gradient, namely the beta effect (variation of Coriolis parameter with latitude). Such a motion deviated from the steering flow is often termed beta drift and

Figure 20 Schematic of changes of dissipation and energy input with wind speed in a typical hurricane. WISHE, wind-induced surface heat exchange; MPI, maximum potential intensity. Wang, Y., 2012. Recent research progress on tropical cyclone structure and intensity. Tropical Cyclone Research and Review 1, 254–275.

can be understood based on the nondivergent barotropic model that describes the conservation of absolute vorticity (Chan and Williams, 1987). The governing equation in Cartesian coordinate can be written as

$$\frac{\partial \nabla^2 \psi}{\partial t} + J(\psi, \nabla^2 \psi + f) = 0 \quad [46]$$

where ψ is streamfunction and f is the Coriolis parameter. The linearized equation with no mean flow on an equatorial beta plane can then be written

$$\frac{\partial}{\partial t} \left(\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} \right) + \beta \frac{\partial \psi}{\partial x} = 0 \quad [47]$$

where β is the latitudinal variation of the Coriolis parameter, and is assumed to be constant. Assuming periodic boundary conditions in both x and y directions, the Fourier transform of eqn [47] gives

$$\frac{\partial \Psi}{\partial t} - \frac{ik\beta}{k^2 + l^2} \Psi = 0 \quad [48]$$

where

$$\Psi(k, l, t) = \int_0^{2\pi} \int_0^{2\pi} \psi(x, y, t) e^{i(kx + ly)} dx dy \quad [49]$$

and, k and l are the wave numbers in x and y directions, respectively. The solution for eqn [48] is oscillatory

$$\Psi(k, l, t) = A(k, l) e^{-i\omega t} \quad [50]$$

Substituting eqn [50] into eqn [48] yields $A(k, l) = \Psi(k, l, 0)$, and

$$\omega = -\frac{k\beta}{k^2 + l^2} \quad [51]$$

The streamfunction at any time t is then given by the inverse transform of $\Psi(k, l, t)$ as

$$\psi(x, y, t) = \frac{1}{2\pi} \sum_k \sum_l A(k, l) e^{-i(kx + ly + \omega t)} \quad [52]$$

Given the initial condition $\psi(x, y, 0)$, we can then solve for $\psi(x, y, t)$ using eqns [49]–[52]. Note that since the wave number l in the y direction only appears as l^2 in eqn [51], the solution will be symmetric about the x -axis.

Given an initial distribution of the streamfunction for an initially axisymmetric vortex, the evolution is shown in Figure 21(a). The vortex is elongated westward with time as a result of the dispersive effect of Rossby waves. The dispersion relation given by eqn [51] implies that longer waves have larger westward phase speeds than shorter waves. Since the waves

Figure 21 Streamfunction fields at 0, 36, and 72 h for the analytical (a) linear model and (b) the nonlinear numerical solution with an initially axisymmetric cyclonic vortex. Chan, J.C.L., Williams, R.T., 1987. Analytical and numerical studies of the beta-effect in tropical cyclone motion. Part I: Zero mean flow. *Journal of Atmospheric Sciences* 44, 1257–1265.

representing the outer circulation have lower-wave numbers than those representing the inner circulation, the outer part of the vortex propagates westward faster than the inner part, resulting in a stretching of the vortex westward.

The asymmetry in the streamfunction also implies an asymmetry in the wind fields. When the nonlinear advection is included, vortex will propagate poleward and westward (Figure 21(b)). This propagation is called beta drift since it is caused purely by the beta effect. The beta drift is associated with the development of the so-called ventilation flow over the vortex center as we can see from the development of asymmetric streamfunction shown in Figure 22, where the asymmetric ventilation flow advects the vortex toward the northwest (southwest) in the Northern (Southern) Hemisphere.

The developed asymmetric circulation, anticyclonic to the east and cyclonic to the west, is called the beta gyres. Its development can be understood through the conservation of

the absolute vorticity. To the east of the vortex center, the southerly brings low earth vorticity to the north, generating a negative vorticity anomaly and thus anticyclonic circulation. To the west, on the other hand, the northerly brings high earth vorticity to the south, generating positive vorticity anomaly and thus cyclonic circulation. The northerly flow between the two beta gyres advects the vorticity of the vortex poleward. On the other hand, the primary cyclonic circulation of the vortex may rotate the counter-rotating gyres cyclonically. In general, a quasi-steady solution can be reached as seen in Figure 22. As a result, the counter-rotating gyres are oriented in northeast-southwest direction and the ventilation flow is a southeasterly over the vortex center and thus a northwestward propagation of the hurricane in the Northern Hemisphere (Fiorino and Elsberry, 1989).

Since the phase speed of Rossby waves is a function of wavelength as discussed previously, it is expected that the beta

Figure 22 Temporal evolution of the asymmetric streamfunction at (a) 6 h, (b) 12 h, (c) 24 h, and (d) 72 h. The domain in each panel is 2400×2400 km centered at the vortex. drift would be sensitive to the outer wind profile of the initial vortex that reflects larger wavelengths. But it would not be sensitive to the inner core intensity that composes mostly the shorter wavelengths. In addition, the beta drift of a hurricane vortex described so far is based on unforced barotropic dynamics. In real atmosphere, the beta drift can be considerably affected by both the baroclinic and diabatic effects. For example, the westward motion component of the beta drift of a diabatic baroclinic hurricane vortex would be reduced by the downward penetrative effect of the upper-level anticyclonic circulation (Wang and Holland, 1996b,c). In addition to the beta drift caused by the earth's vorticity gradient, the PV gradient in the hurricane environment can lead to a similar drift of the hurricane vortex from the deep-layer mean steering flow (Shapiro, 1992).

In addition to the beta effect, vertical wind shear may also cause a hurricane vortex to deviate from the deep-layer mean flow (Wu and Emanuel, 1993). Divergent circulation driven by diabatic heating can lead to the development of an anticyclonic circulation above the deep cyclonic hurricane vortex. In a vertical wind shear, the upper-level anticyclonic anomalies would be displaced downshear relative to the lower part of the hurricane vortex. The downward penetration flow of the upper-level anticyclonic PV anomaly associated with the upper-level anticyclone will steer the lower part of the hurricane vortex to the left (right) of the shear in the Northern (Southern) Hemisphere. The magnitude of such a leftward (rightward in the Southern Hemisphere) propagation can be comparable to the beta drift and is determined by static stability, latitude, storm size and intensity, and vertical shear vector (Wu and Emanuel, 1993).

Hurricane Predictability

Synopsis

This article reviews the current understanding of tropical cyclone predictability. General concepts regarding atmospheric predictability are first presented, and are then related to tropical cyclones. A central theme is that error growth associated with moist convection limits the intrinsic predictability of tropical cyclone intensity, which is similar to what limits predictability in the midlatitudes. Meanwhile, practical predictability is limited by convective amplification of errors in specifying the initial cyclone vortex, the background state, particularly near gradients, and in the aerosol concentration. Predictability is case dependent and appears to be lower in environments with higher convective instability and wind shear.

Introduction

Understanding sources of tropical cyclone forecast uncertainty and error growth is essential for future improvement of hurricane forecasts. Although some aspects of tropical cyclone forecasts have been improved considerably during the past decade, they are still plagued by significant errors. While today's 48-h position forecast is as accurate as the 24-h forecast 10 years ago, there has been little improvement in intensity forecasts (Figure 1). In addition, forecasting cyclogenesis remains a challenge, and predictions of rapid intensification (RI) and decay remain particularly problematic. The intent of this article is to serve as a review of the current understanding of tropical cyclone predictability.

To better understand tropical cyclone predictability, one must first understand some fundamental concepts of general atmospheric predictability. Previous research has elucidated two types of predictability: practical predictability is the ability to predict based on currently available procedures, and intrinsic predictability is the extent to which prediction is possible if an optimum procedure is used. Practical predictability is limited by uncertainties in the forecast model and initial conditions, which are presently quite large. Constraints on practical predictability include the sufficiency of observations (including accuracy, quantity, and usability), data assimilation, and modeling. Meanwhile, intrinsic predictability is that which can be attained

with nearly perfect knowledge of both the atmospheric state and physics.

Both practical and intrinsic predictability are flow-dependent and are limited during regime transition. For example, the large-scale atmosphere can be likened to the Lorenz model, as different flow regimes are similar to the famous Lorenz attractors (e.g., Figure 2). Most of the unpredictability in the model arises from unsteady behavior between the two attractors, and the atmosphere likewise lacks predictability between regimes.

These ideas appear to be applicable to mesoscale flows as well. For example, recent work has shown that small variations in initial conditions can produce very different realizations of a midlatitude squall line; a generalization of this is shown in Figure 3(a). Though initial differences might be far less than typical analysis error, some realizations develop a severe squall line after 12–18 h, while others generally demonstrated little or no linear development. Particularly large differences occurred over a very small spectrum of initial condition perturbations, similar to the unstable region in Figure 2. In summary, practically immeasurable error can grow rapidly when the background state straddles very different regimes, particularly in the presence of moist convection.

The growth of small-scale error has been a subject of a number of other recent studies. Generally speaking, small-scale and small-amplitude initial condition perturbations may lead to substantial mesoscale differences from 24 to 36 h

Figure 1 The evolution of National Hurricane Center forecast error in terms of tropical cyclone (a) track and (b) maximum 10-m winds.

Figure 2 A solution to the Lorenz 63 model with the unstable region and attractors denoted.

into a forecast. These errors first grow from convective instability in regions of moist convection and saturate convective scales several hours into the forecast. Subsequent error growth occurs through geostrophic adjustment and/or cold pool dynamics, leading to mesoscale error saturation on a time scale of order $1/f$. The balanced component of the mesoscale error grows further in the presence of large-scale baroclinicity, which eventually limits large-scale predictability as well. This type of error growth, which can be found in a variety of midlatitude systems, in general explains why warm-season precipitation remains the least-accurate forecast element at all scales.

Despite the lack of predictability associated with warm-season convection, cool-season precipitation prediction fares much better. This is due to the fact that small-scale convective processes dominate warm-season precipitation, while synoptic-scale systems tend to force cool-season precipitation. This is in agreement with the finding that the rate of error growth is likely positively related to the magnitude and areal coverage of convective available potential energy (CAPE).

Predictability Concepts Applied to Tropical Cyclones

Before examining how general atmospheric predictability concepts apply to tropical cyclones, we take a brief detour to explain the general mechanism by which they intensify. Though there is no shortage of studies that have investigated factors influencing tropical cyclone intensification, any increase in tropical cyclone strength must occur through an inward radial advective flux of vorticity, which itself is driven by diabatic heating associated with moist convection. In terms of vertical vorticity tendency, stretching is the primary 'driver' of this process. Viewed through this lens, any process that enhances or disrupts latent heating and vortex stretching can potentially impact tropical intensity.

The sensitivity of hurricane intensity change to latent heating helps to clarify reasons for the disparity between hurricane track and intensity forecast improvement. Hurricane movement is generally controlled by the large-scale horizontal wind, of which forecasts have consistently improved during recent decades. However, tropical cyclone intensity is more strongly related to difficult-to-predict warm-season convection. The remainder of this section will examine how current ideas regarding predictability apply to tropical cyclones.

Intrinsic Predictability in Quiescent Environments

As a first step in examining the predictability of tropical cyclones, it is instructive to quantify intrinsic intensity predictability in environments with no mean flow or background asymmetries. A number of recent studies have used ensemble forecasts with idealized models to investigate tropical cyclone forecast differences that arise as a result of tiny initial condition perturbations. Though there are some differences in the methods and results, all of these studies have found for steady-state intense cyclones that the largest differences in maximum wind between any two ensemble members were typically $5\text{--}10\text{ m s}^{-1}$. In addition, ensemble standard deviation appears to be about $3\text{--}4\text{ m s}^{-1}$. Such differences are commensurate with discrepancies that arise from integrating exactly the same initial conditions on different supercomputer nodes.

Figure 3 The sensitivity to small changes in initial conditions from recent studies simulating the development of (a) a squall line (source data is presented in Melhauser, C., Zhang, F., 2012. Practical and intrinsic predictability of severe and convective weather at the mesoscales. *Journal of Atmospheric Sciences* 69, 3350–3371) and (b) a tropical cyclone (source data is presented in Zhang and Sippel, 1999).

Rapid Intensification

RI, which is roughly defined as an increase in maximum surface wind speed of about 15 m s^{-1} over a 24-h period, is an important aspect of tropical cyclone intensification. About 20–30% of all tropical cyclones (the number varies by ocean basin) undergo RI at least once during their lifetimes. More importantly, RI occurs in a great majority $\sim 70\%$ of major tropical cyclones ($>51 \text{ m s}^{-1}$). Because of the frequent occurrence and potentially severe implications of a tropical cyclone undergoing RI, accurate RI forecasts could be very valuable.

Unfortunately, RI is the most problematic and error-prone facet of tropical cyclone intensity forecasting. It appears that environmental parameters of rapidly intensifying tropical cyclones are not much different than those of cyclones intensifying more slowly. This indicates that the rate of intensification is only weakly dependent on the environmental conditions, and in favorable intensification environments RI is more strongly controlled by internal dynamical processes. This is consistent with knowledge that local moist convection plays a critical role in RI, which should intrinsically limit its predictability. Thus, deterministic forecasts may never predict RI very well, suggesting the need for probabilistic forecasts.

The positive relationship between error growth and convective instability might also apply to RI. Recent work has shown that RI in at least a few cyclones commences when reservoirs of high convective instability are released, allowing for a significant expansion in central-core convection. For example, one recent study examined tropical storm Humberto (2001) immediately before it commenced RI to a hurricane. They found that high- θ_e air in the storm's inflow contributed to a buildup in CAPE, which was not immediately consumed due to a mesoscale inversion. The inversion, which was associated with a stratiform rain region, allowed CAPE to reach at least $2500 \text{ m}^2 \text{ s}^{-2}$ before convection erupted. The convection that ensued became the hurricane's eyewall, and RI immediately followed. Meanwhile, another study examined Hurricane Lili (2002) and found that RI commenced when a reservoir of high- θ_e air was released from the eye into the eyewall. They suggested that the reservoir was insufficiently large to sustain the entire RI cycle, but instead it acted to trigger the process. These findings are consistent with the general trend of rapidly intensifying storms to be in more unstable environments than steady-state storms (e.g., Figure 4).

Tropical Cyclone Structure and Size

Much of the uncertainty in tropical cyclone forecasts likely arises in the specification of the initial vortex. For example, the intensification of Hurricanes Danielle and Karl (2010) has been shown to be most sensitive to the initial circulation and thermodynamic fields associated with the pregenesis systems. The largest sensitivity was in the lower troposphere, close to the circulation maximum, and sensitivity to the surrounding environment was smaller.

Though no published work has directly examined the impact of a tropical cyclone's size or structure upon its intrinsic predictability, recent studies suggest that smaller tropical cyclones might be fundamentally less predictable

Figure 4 Hurricane intensity behavior as a function of environmental vertical wind shear and convective instability. Source data for this figure is presented in DeMaria, M., 2009. A simplified dynamical system for tropical cyclone intensity prediction. *Monthly Weather Review* 137, 68–82.

than larger ones. For example, new research has revealed that tropical cyclones with compact inner cores rapidly intensify more often than their larger counterparts. In addition, these compact cyclones are driven more strongly by inner-core convection and dynamics, whereas storms with larger inner cores are more strongly influenced by external forcing. Thus, the propensity for RI in small tropical cyclones appears to be a reflection of their sensitivity to unpredictable, small-scale convective processes. Nevertheless, much more work is needed to precisely assess the impact of tropical cyclone size upon predictability.

Cold Pool Dynamics and Cyclogenesis

As with midlatitude systems, convection and cold pool dynamics can rapidly amplify small analysis errors in short-term tropical cyclone forecasts. Similar to the midlatitude squall line case mentioned in the Section [Introduction](#), very small subsets of initial condition perturbations can make the difference between strongly developing and nondeveloping realizations of a tropical cyclone (Figure 3(b)). Also, small differences in moisture and instability can strongly impact the location, extent, and strength of cold pools, which affects the incipient low-level mesoscale vortex. If placed correctly, spreading cold pools can potentially destroy the initial low-level vortex, affecting both maximum intensity and size of the subsequent cyclone.

This demonstrates a particular difficulty in forecasting tropical cyclone formation. Significant low-level vortex amplification generally does not begin until sustained convection occurs very near or over the vortex center (i.e., vortex stretching), so the location of a cold pool can have a profound effect on an incipient tropical cyclone. If a cold pool develops but does not disrupt near-center convection, then genesis may proceed quickly, perhaps leading to RI. However, any disruption of convection requires time for the near-center planetary boundary layer to recover, which can take at least 12 h. If subsequent cold pools further inhibit convection over the center, then genesis could take even longer to commence. The lack of predictability associated with cold pools and mesoscale convection suggests the need for probabilistic forecasts of tropical cyclone formation.

Nonhomogenous Environments, Background Uncertainty, and Cyclogenesis

Nonhomogenous backgrounds and background forecast uncertainty can also strongly modulate the predictability of tropical cyclones. For example, a recent study used an ensemble forecast initialized with an ensemble Kalman filter (EnKF) to investigate reasons for unusually large forecast uncertainty associated with Hurricane Humberto (2007). Humberto rapidly developed off the upper Texas coast, and operational models completely failed to predict the storm's genesis, which resulted in extremely poor official forecasts. Though EnKF analysis uncertainty was fairly low, subsequent ensemble forecast spread grew rapidly. Intensification of the incipient cyclone was particularly affected by varying surface moisture and convective instability, which was related to the strength of a nearby front and proximity of the cyclone to the front. These discrepancies directly impacted the ability of convection to amplify the incipient vortex so that RI began immediately in some ensemble members, while others exhibited little intensity change.

Another recent study examined the effect of dry midlevel air on tropical cyclone formation by varying the distance between a relative humidity gradient and the center of an incipient vortex. They found that cyclone strength and structure in multiday forecasts was fairly sensitive to the initial location of the dry-air boundary when the boundary closed to within 150 km of the cyclone center. This is most relevant to cyclogenesis since the centers of developing systems can move discretely, jumping between convective complexes, and since weaker cyclones are more susceptible to infiltration of nearby dry air than are stronger systems.

Vertical Wind Shear and RI

Vertical wind shear can have profound impacts on the predictability of tropical cyclones. In idealized ensemble simulations with only very tiny initial condition perturbations, ensemble spread increases dramatically for environments of weak to moderate vertical wind shear. This is particularly true for the genesis and RI periods, where differences in maximum wind speed between different members can exceed 40 m s^{-1} . Ultimately, in the presence of vertical wind shear, random initial noise may change the onset and ending of RI by as much as 1–2 days.

The reason for these large differences is the randomness and chaotic nature of moist convection, which is similar to a number of aforementioned studies. Differences in moist convection first alter the tilt amplitude and angle of the vortex, which later significantly changes the precession and vortex alignment. Tropical cyclones rapidly intensify immediately after the tilt and local shear reach their minima, but the time at which this occurs is different in each member.

Some recent observational studies likewise suggest decreased predictability of tropical cyclones in the presence of strong vertical wind shear. A number of papers have investigated cases where tropical cyclone maximum intensity vacillated considerably over periods of less than a day. In the case of 6-h Hurricane Claudette (2003), vertical wind shear was directly ascribed to the quick weakening of the system, though there were insufficient observations to draw conclusions regarding the cause of the preceding intensification. Meanwhile, strong shear was also

responsible for both quick intensification and subsequent weakening of Tropical Storms Gabrielle (2004) and Edouard (2002) in the Gulf of Mexico.

The details of convection and cold pool evolution appear to be the mechanisms through which shear caused large intensity fluctuations in the observed cases. Vertical wind shear induces stronger, deeper inflow and much larger CAPE and helicity in the downshear region of a sheared storm, a combination that favors potentially explosive rotating convection. If that convection is sufficiently close to the cyclone core of high vorticity, then extreme RI can ensue (e.g., Tropical Storm Gabrielle intensified by 22 hPa in less than 3 h). Just as the downshear region is favorable for convection, the area upshear is quite unfavorable, largely because of shear-induced subsidence. This subsidence can dry a deep layer, which occasionally entrains into the downshear convection, resulting in cool downdrafts and cold pools. Such cold pools have been described as an 'antifuel' for tropical cyclones because of their ability to inhibit convection and quickly diminish the tropical cyclone vortex.

There are of course, several differences between the above observed and idealized ensemble cases. First, there has been no explicit examination of the predictability in the observed cases, though they were associated with a large degree of forecast error. In addition, such erratic intensity evolution and strong dependence upon convection is highly symptomatic of a lack of intrinsic predictability. Another difference is that all the idealized ensemble members eventually reached steady-state hurricane intensity, whereas the observed cases weakened soon after they intensified. This difference is probably due to the difference in vertical wind shear between the modeled and the observational studies. In the idealized ensemble, the strongest shear imposed was 5 m s^{-1} , whereas the observed storms all had greater than 10 m s^{-1} of vertical wind shear. The difference in development is consistent with what is shown in Figure 4.

Atmospheric Aerosols and Convection

New research also suggests that small variations in atmospheric aerosol concentrations can impact the predictability of tropical cyclones. Ensemble experiments with a model that accounts for microphysics–aerosol interactions have shown a nonlinear (albeit monotonically negative) relationship between the initial aerosol concentration and subsequent cyclone maximum intensity. When the initial number concentration increased from 100 to 1000 cm^{-3} , mean intensity decreased by roughly 15 m s^{-1} after 24 h. However, roughly half this intensity reduction was obtained by increasing the initial concentration to only 101 cm^{-3} . While more work is needed to fully assess the impact of aerosols on tropical cyclones, these results suggest that error growth associated with moist convection is amplified by uncertainty in background aerosol concentration.

Summary and Discussion

An underlying finding in most recent research is that error growth associated with moist convection limits the intrinsic predictability of tropical cyclones. As with midlatitude convection, practically immeasurable initial errors can grow upscale to introduce large forecast errors, particularly during RI.

Aside from tiny initial perturbations, typical error sources include uncertainty in specifying the initial cyclone vortex, uncertainty in the background state, particularly near gradients, and uncertainty in aerosol concentration.

Though forecast error can explosively grow in some tropical cyclone forecasts, other cases are relatively predictable implying that ensemble spread is case dependent. Thus, some tropical cyclone forecasts are particularly sensitive to initial condition errors, while others are not. In terms of intensity forecasts, the least predictable cases are likely to be those with high error growth potential of near-center convection, possibly associated with the consumption of CAPE. This most obviously includes environments that are favorable for intensification, since RI is usually a possibility in favorable environments. In addition, otherwise favorable environments with moderate vertical wind shear can also lead to very large error growth due to the buildup of CAPE and the influence of cold pools in sheared tropical cyclones. Particularly low predictability also appears to accompany storms that are in locally favorable environments but with less favorable conditions nearby.

The fact that some tropical cyclones have higher predictability suggests that small-scale convective processes do not always control cyclone strength. In these cases, there could be strong modulation of convection by the more predictable large-scale environment, or perhaps forcing associated with the mean secondary circulation of the parent vortex becomes more important than smaller scale processes. This is supported by the fact that global models demonstrate skill at forecasting tropical cyclone genesis even though they cannot adequately resolve mesoscale processes. For developed tropical cyclones, enhanced predictability is likely to be found in systems with large inner cores, which are known to have slower intensity changes than those with more compact cores. The midlatitude corollary to cyclones with higher predictability could be that strongly forced cold season precipitation is more predictable than warm-season convection.

The change in predictability from one system to the next illustrates the utility of advanced ensemble prediction systems that can provide event-dependent probabilistic forecasts. Despite the demonstrated benefits of using ensembles in hurricane forecasting, the uncertainty involved with today's operational hurricane forecasts is still mostly based on averaged climatological errors and thus is not case dependent. The body of work discussed herein demonstrates that some events can be associated with very large uncertainty, and operational use of this information would more accurately convey the risks associated with individual systems.

The results of recent experiments that have examined tropical cyclone intrinsic predictability (see Section [Intrinsic Predictability in Quiescent Environments](#)) give some insight into recent intensity error trends. A lower bound of intrinsic predictability, which can be estimated by the ensemble spread in recent intrinsic predictability investigations, is about $3\text{--}4\text{ m s}^{-1}$. This is only slightly higher than current 24-h intensity error, which might mean that average short-term intensity forecast error is already near the limit of intrinsic predictability. If this is true, then even the 36-h forecast error may not improve much more, though there is still room for improvement in longer range intensity forecasts. This hypothesis is supported by the results of a recent multiyear study that examined intensity error in forecasts initialized with EnKF analyses of high-resolution hurricane

data. For all forecast times at and beyond 24 h, bias-corrected intensity error was $4\text{--}5\text{ m s}^{-1}$ on average.

Though assimilation of high-resolution tropical cyclone observations can significantly improve track and intensity forecasts, many aspects of the intrinsic limit of hurricane predictability remain unclear. Even if we are approaching the limit of predictability in short-term maximum intensity forecasts, the scientific community has only recently begun to assess forecasts of hurricane size. This forecast metric is particularly important since it is strongly related to storm surge potential, and storm surge can be the most catastrophic and deadly aspect of a hurricane. Meanwhile, practical predictability associated with realistic initial condition and model errors may be increased through improving our understanding of tropical cyclones, developing better numerical models, and improving data coverage and assimilation techniques. However, as discussed above, there always will be forecast errors due to the inherent limit of predictability arising from initial errors with amplitudes far smaller than any observation or analysis system.

Introduction

‘Hurricane’ is the term used in the Western Hemisphere for one of the general class of strong tropical cyclones, including western Pacific typhoons and similar systems, that are known simply as cyclones in the Indian and southern Pacific Oceans. A tropical cyclone is a low-pressure system which derives its energy primarily from evaporation from the sea in the presence of 1-minute sustained surface wind speeds $>17 \text{ m s}^{-1}$ and the associated condensation in convective clouds concentrated near its center. In contrast, midlatitude storms (low-pressure systems with associated fronts) get their energy primarily from the horizontal temperature gradients that exist in the atmosphere. Structurally, the strongest winds in tropical cyclones are near the Earth’s surface (a consequence of being ‘warm-core’ in the troposphere), while the strongest winds in midlatitude storms are near the tropopause (a consequence of being ‘warm-core’ in the stratosphere and ‘cold-core’ in the troposphere). ‘Warm-core’ refers to being warmer than the environment at the same pressure surface.

A tropical cyclone with the highest sustained wind speeds between 17 and 32 m s^{-1} is referred to as a tropical storm, whereas a tropical cyclone with sustained wind speeds $\geq 33 \text{ m s}^{-1}$ is referred to as a hurricane or typhoon. Once a tropical cyclone has sustained winds $\geq 50 \text{ m s}^{-1}$ it is referred to as a major hurricane or super typhoon. In the Atlantic and eastern Pacific Oceans hurricanes are also classified by the damage they can cause using the Saffir–Simpson scale (Table 1).

The Saffir–Simpson scale categorizes hurricanes on a scale from 1 to 5, with 1 the weakest and 5 the most intense. Major hurricanes correspond to categories 3 and higher. The reasons that some disturbances intensify to a hurricane, while others do not, are not well understood. Neither is it clear why some tropical cyclones become major hurricanes, while others do not. Major hurricanes produce 80–90% of the United States hurricane-caused damage despite accounting for only one-fifth of all landfalling tropical cyclones. Only two category 5 hurricanes made landfall on the mainland United States (Florida Keys 1935 and Camille 1969). Recent major hurricanes to make landfall on the United States were Hurricanes Bonnie and Georges in 1998, and Bret and Floyd in 1999.

As with large-scale extratropical weather systems, the structure and evolution of a tropical cyclone is dominated by the fundamental contradiction that while the airflow within a tropical cyclone represents an approximate balance among forces affecting each air parcel, slight departures from balance are essential for vertical motions and resulting clouds and precipitation, as well as changes in tropical cyclone intensity. As in extratropical weather systems, the basic vertical balance of forces in a tropical cyclone is hydrostatic except in the eyewall, where convection is superimposed on the hydrostatic motions. However, unlike in extratropical weather systems, the basic horizontal balance in a tropical cyclone above the boundary layer is between the sum of the Coriolis ‘acceleration’ and the centripetal ‘acceleration’, balanced by the horizontal pressure gradient force. This balance is referred to as gradient balance, where the Coriolis ‘acceleration’ is defined as the horizontal velocity of an air parcel, v , times the Coriolis parameter, f . (f is the Coriolis parameter ($f = 2\Omega \sin \phi$), where Ω is the angular velocity of the Earth ($7.292 \times 10^{-5} \text{ s}^{-1}$) and ϕ is latitude. The Coriolis parameter is zero at the equator and 2Ω at the pole.) Centripetal ‘force’ is defined as the acceleration on a parcel of air moving in a curved path, directed toward the center of curvature of the path, with magnitude v^2/r , where v is the horizontal velocity of the parcel and r the radius of curvature of the path. The centripetal force alters the original two-force geostrophic balance and creates a nongeostrophic gradient wind.

The inner region of the tropical storm, termed the cyclone ‘core’, contains the spiral bands of precipitation, the eyewall, and the eye that characterize tropical cyclones in radar and satellite imagery (Figure 1). The primary circulation – the tangential or swirling wind – in the core becomes strongly axisymmetric as the cyclone matures. The strong winds in the core, which occupies only 1–4% of the cyclone’s area, threaten human activities and make the cyclone’s dynamics unique. In the core, the local Rossby number is always >1 and may be as high as 100. The Rossby number indicates the relative magnitude of centrifugal (v/r) and Coriolis (f) accelerations, $Ro = V/fr$, where V is the axial wind velocity, f the Coriolis parameter, and r the radius from the storm center. An approximate breakdown of regimes is: $Ro < 1$, geostrophic

Table 1 Saffir–Simpson scale of hurricane intensity

Category	Pressure (hPa)	Wind (ms^{-1})	Storm surge (m)	Damage
1	>980	33–42	1.0–1.7	Minimal
2	979–965	43–49	1.8–2.6	Moderate
3	964–945	50–58	2.7–3.8	Extensive
4	944–920	59–69	3.9–5.6	Extreme
5	<920	≥ 70	≥ 5.7	Catastrophic

Figure 1 NOAA-14 AVHRR multispectral false color image of Hurricane Floyd at 2041 UTC, 13 September 1999 about 800 km east of southern Florida. Photo courtesy of NOAA Operationally Significant Event Imagery website: <http://www.osei.noaa.gov/>.

flow; $Ro > 1$, gradient flow; and $Ro > 50$, cyclostrophic flow. When the Rossby number significantly exceeds unity, the balance in the core becomes more cyclostrophic, where the pressure gradient force is almost completely balanced by the centrifugal ‘force’. The time scales are such that air swirling around the center completes an orbit in much less than a pendulum day (defined as $1/f$).

When the atmosphere is in approximate horizontal and vertical balance, the wind and mass fields are tightly interconnected. The distribution of a single mass or momentum variable may be used as a starting point to infer the distribution of all other such variables. One such variable is potential vorticity (PV), approximately equal to the vorticity times the

thermal stratification, which is related to the three-dimensional mass and momentum fields through an inverse second-order Laplacian-like operator. The benefit of such a relationship is that PV variations in a single location are diagnostically related to variations in mass and wind fields at a distance. Areas of high PV correspond locally to low mass, or cyclones, while areas of low PV correspond to anticyclones.

Typical extratropical weather systems contain high PV values around $0.5 \times 10^{-6} \text{ m}^2 \text{ s}^{-1} \text{ K kg}^{-1}$ (0.5 PVU) to 5 PVU, whereas typical values in the tropical cyclone core are ≥ 10 PVU. **Figure 2** shows the wind and mass fields associated with an idealized axially symmetric tropical cyclone PV anomaly with the PV concentrated near the surface rather than in

Figure 2 v (gradient wind) (ms^{-1}) and θ' (perturbation potential temperature) (K, top panel); and h' (geopotential height perturbation) (dm) and ζ/f (bottom panel) for a warm core, lower cyclone. The tropopause location is denoted by the bold solid line, and the label 0 on the horizontal axis indicates the core (and axis of symmetry) of the disturbance. The equivalent pressure deviation at the surface in the center of the vortex is -31 hPa. a vertical column. The cyclonic anomaly (positive in the Northern Hemisphere) is associated with a cyclonic circulation that is strongest at the level of the PV anomaly near the surface, and decreases upward. Temperatures are anomalously warm above the PV anomaly (isentropic surfaces are deflected downward). While consistent with the simple PV distribution, the wind and mass fields are also in horizontal and vertical balance. The tropical cyclone being a warm-core vortex, the PV inversion dictates that the winds that swirl about the center decrease with increasing height, but they typically fill the depth of the troposphere. If the PV reaches values ≥ 10 PVU, the inner region winds can become intense, as in Hurricane Gloria (Figure 3). Gloria had PV values exceeding 500 PVU just inside the radius of maximum winds of 15 km where the axisymmetric mean tangential winds exceeded 65 m s^{-1} .

Many features in the core, however, persist with little change for (pendulum) days (mean life span of a tropical cyclone is about 5–10 days). Because these long lifetimes represent tens or hundreds of orbital periods (~ 1 h), the flow is nearly balanced. Moreover, at winds $> 35 \text{ m s}^{-1}$, the local Rossby radius of deformation is reduced from its normal $\sim 10^3$ km to a value comparable with the eye radius. The Rossby radius of deformation is the ratio of the speed of the relevant gravity wave mode and the local vorticity, or, equivalently, the ratios of the Brunt–Väisälä and inertial frequencies. This scale indicates the amount of energy that goes into gravity waves compared with inertial acceleration of the wind. In very intense tropical cyclones, the eye radius may approach the depth of the troposphere (15 km), making the aspect ratio unity. Thus, the dynamics near the center of a tropical cyclone are so exotic

that conditions in the core differ from the Earth's day-to-day weather as much as the atmosphere of another planet does.

Climatology

There are 80–90 tropical cyclones worldwide per year, with the Northern Hemisphere having more tropical cyclones than the Southern Hemisphere. Table 2 shows that of the 80–90 tropical cyclones, 45–50 reach hurricane or typhoon strength and 20 reach major hurricane or super typhoon strength. The western North Pacific (27 tropical cyclones), eastern North Pacific (17 tropical cyclones), south-west Indian Ocean (10 tropical cyclones), Australia/south-west Pacific (10 tropical cyclones), and North Atlantic (10 tropical cyclones) are the major tropical cyclone regions. There are also regional differences in the tropical cyclone activity by month with the majority of the activity in the summer season for each basin. Hence, in the Pacific, Atlantic, and North Indian Ocean the maximum numbers of tropical cyclones occur in August through October, while in the South Pacific and Australia regions the maxima are in February and March. In the South Indian Ocean, the peak activity occurs in June. In the western North Pacific, Bay of Bengal, and South Indian Ocean regions tropical cyclones may occur in any month, while the other regions at least one tropical cyclone-free month occurs per year. For example, in the North Atlantic, there has never been tropical cyclone activity in January.

Some general conclusions can be drawn from the global distribution of tropical cyclone locations (Figure 4(a)). Tropical

Table 2 Mean annual frequency, standard deviation (σ) and percentage of global total of the number of tropical storms (winds $\geq 17 \text{ m s}^{-1}$), hurricane-force tropical cyclone (winds $\geq 33 \text{ m s}^{-1}$), and major hurricane-force tropical cyclone (winds $\geq 50 \text{ m s}^{-1}$). Dates in parentheses provide the nominal years for which accurate records are currently available

Tropical cyclone basin	Tropical storm annual frequency (σ)	% of total	Hurricane annual frequency (σ)	% of total	Major hurricane annual frequency (σ)	% of total
Atlantic (1944–00)	9.8 (3.0)	11.4	5.7 (2.2)	12.1	2.2 (1.5)	10.9
NE Pacific (1970–00)	17.0 (4.4)	19.7	9.8 (3.1)	20.7	4.6 (2.5)	22.9
NW Pacific (1970–00)	26.9 (4.1)	32.1	16.8 (3.6)	35.5	8.3 (3.2)	41.3
N Indian (1970–00)	5.4 (2.2)	6.3	2.2 (1.8)	4.6	0.3 (0.5)	1.5
SW Indian (30–100° E) (1969–00)	10.3 (2.9)	12.0	4.9 (2.4)	10.4	1.8 (1.9)	9.0
Australian/SE Indian (100–142° E) (1969–00)	6.5 (2.6)	7.5	3.3 (1.9)	7.0	1.2 (1.4)	6.0
Australian/SW Pacific (142° E) (1969–00)	10.2 (3.1)	11.8	4.6 (2.4)	9.7	1.7 (1.9)	8.5
Global (1970–00)	86.1 (8.0)		47.3 (6.5)		20.1 (5.7)	

cyclone formation is confined to a region approximately 30° N and 30° S, with 87% of them located within 20° of the Equator. There is a lack of tropical cyclones near the Equator, as well as in the eastern South Pacific and South Atlantic basins. From these observations there appear to be at least five necessary conditions for tropical cyclone development.

- Warm sea surface temperature (SST) and large mixed-layer depth (i.e., the thickness of the mixed layer, defined as the depth of

the sharp temperature inversion (also referred to as the thermocline) between the cooler bottom water and the warmer near surface water). Numerous studies suggest a minimum SST criterion of 26 °C for development. The warm water must also have sufficient depth (i.e., 50 m). Comparison of Figures 4(a) and 4(b), the annual mean global SST, shows the strong correlation between regions where the SST is $> 26^\circ \text{C}$ and annual tropical cyclone activity. An SST of $> 26^\circ \text{C}$ is sufficient but not necessary for tropical

Figure 4 (a) Frequency of tropical cyclones per 100 years within 140 km of any point. Solid triangles indicate maxima, with values shown. Period of record is shown in boxes for each basin. (b) Annual sea surface temperature distribution ($^{\circ}\text{C}$).

cyclone activity, as is evidenced by the regions with tropical cyclone activity when the SST $< 26^{\circ}\text{C}$. Some of the discrepancy exists because storms that form over regions where the SST is $> 26^{\circ}\text{C}$ are advected poleward during their life cycle. However, tropical cyclones are observed to originate over regions where the SST $< 26^{\circ}\text{C}$. These occurrences are not many, but the fact that they exist suggests that other factors are important.

- **Background Earth vorticity.** Tropical cyclones do not form within 3° of the Equator. The Coriolis parameter vanishes at the Equator and increases to extremes at the poles. Hence, a threshold value of Earth vorticity (f) must exist for

a tropical cyclone to form. However, the likelihood of formation does not increase with increasing f . Thus, nonzero Earth vorticity is necessary, but not sufficient to produce tropical cyclones.

- **Low vertical shear of the horizontal wind.** In order for tropical cyclones to develop, the latent heat generated by the convection must be kept near the center of the storm. Historically, shear was thought to ‘ventilate’ the core of the cyclone by advecting the warm anomaly away. The ventilation argument suggests that if the storm travels at nearly the same speed as the environmental flow in which it is embedded then its heating remains over the disturbance

center. However, if it is moving slower than the mean wind at upper levels then the heating in the upper troposphere is carried away by the mean flow. Recent analysis suggests that the effect of shear is to force the convection into an asymmetric pattern such that the convective latent heat release forces flow asymmetry and irregular motion rather than intensification of the symmetric vortex. Thus, if the vertical shear is too strong ($>16 \text{ m s}^{-1}$) then existing tropical cyclones are ripped apart and new ones cannot form.

- **Low atmospheric static stability.** Static stability is the ability of a fluid to become turbulent (unstable) or laminar (stable) due to the effects of buoyancy neglecting all other inertial effects of motion. The troposphere must be potentially unstable to sustain convection for an extended period. Typically measured as the difference between the equivalent potential temperature, θ_e , at the surface and 500 hPa, instability must typically be $>10 \text{ K}$ for convection to occur. This value is usually satisfied over tropical oceans.
- **Tropospheric humidity.** The higher the midlevel humidity, the longer a parcel of air can remain saturated as it entrains the surrounding air during its ascent. Vigorous convection occurs if the parcel remains saturated throughout its ascent. A relative humidity of 50–60% at lower to midlevels (700–500 hPa) is often sufficient to keep a parcel saturated during ascent. This condition is regularly evident over tropical oceans.

These conditions are usually satisfied in the summer and fall seasons for each tropical cyclone basin. However, even when all of the above conditions are favorable, tropical cyclones don't necessarily form. In fact, there is growing evidence for significant interannual variability in tropical cyclone activity, where numerous tropical cyclones form in a given basin over a week to 10 days, followed by 2–3 weeks with little or no tropical cyclone activity. **Figure 5** shows just such an active period in the Atlantic basin in mid-September 1999, where two hurricanes (Floyd and Gert), both major, and an unnamed tropical depression formed within a few days of each other. During these active phases almost every disturbance makes at least tropical storm strength, whereas in the inactive phase practically none of the disturbances intensify. The two hurricanes and unnamed depression in **Figure 5** represented the second 10-day active period during the summer of 1999. An earlier period in mid-August also resulted in the development of three hurricanes (Brett, Cindy, and Dennis), two of which were major, as well as a tropical storm (Emily). There is speculation that the variability is related to the propagation of a global wave. Because the SST, static stability, and Earth vorticity don't vary that much during the season, the interannual variability is most likely related to variations in tropospheric relative humidity and vertical wind shear.

It has long been recognized that the number of tropical cyclones in a given region varies from year to year. The exact causes of this remain largely speculative. The large-scale global

variations in atmospheric phenomena such as the El Niño Southern Oscillation (ENSO) and the Quasi-Biennial Oscillation (QBO) appear to be related to annual changes in the frequency of tropical cyclone formation, particularly in the Atlantic Ocean. The ENSO phenomenon is characterized by warmer SSTs in the eastern South Pacific and anomalous winds over much of the equatorial Pacific. It influences tropical cyclone formation in the western North Pacific, South Pacific, and even the North Atlantic.

During the peak phase of the ENSO, often referred to as El Niño (which usually occurs during the months July–October), anomalous westerly winds near the Equator extend to the dateline in the western North Pacific acting to enhance the intertropical convergence zone (ITCZ) in this area, making it more favorable for formation of tropical cyclones. Another effect of the El Niño circulation is warmer SST in the eastern South Pacific. During such years, tropical cyclones form closer to the Equator and farther east. Regions such as French Polynesia, which are typically unfavorable for tropical cyclones owing to a strong upper-level trough, experience numerous tropical cyclones. The eastern North Pacific is also affected by the El Niño through a displacement of the ITCZ south to near 5° N. Additionally, the warm ocean anomaly of El Niño extends to near 20° N, which enhances the possibility of tropical cyclone formation. The result is an average increase of two tropical cyclones during El Niño years. Cyclones also develop closer to the Equator and farther west than during a normal year.

The QBO is a roughly 2-year oscillation of the equatorial stratosphere (30–50 hPa) winds from easterly to westerly and back. The phase and magnitude of QBO are associated with the frequency of tropical cyclones in the Atlantic. Hurricane activity is more frequent when the 30-hPa stratospheric winds are westerly. The exact mechanism by which the QBO affects tropical cyclones in the troposphere is not clear; however, there are more North Atlantic tropical cyclones when the QBO is in the westerly phase than when it is in the easterly.

Tropical Cyclogenesis

Enthalpy is a thermodynamic state function defined for an ideal gas as the temperature times the specific heat at constant pressure plus a constant. For a system like the atmosphere which consists of a mixture of components the total enthalpy is the mass-weighted sum of the enthalpies of each component. Thus, the total enthalpy for a system consisting of a mixture of dry air, water vapor, and liquid water is defined as a constant plus the temperature times the sum of the specific heats at constant pressure for each component times the masses of each component, respectively. In an adiabatic, reversible process, the total enthalpy is conserved, although the component enthalpies may not be due to the exchange of enthalpy between components in phase changes. Most of the energy needed for tropical cyclones to form and maintain themselves is realized through the difference in enthalpy between the warm near-surface waters of the tropical ocean and the tropospheric column. The process of bringing the late-summer tropical troposphere into thermodynamic equilibrium with the sea surface at 28–30 °C, mainly through the irreversible energy

transfer from the ocean to the air by evaporation, can produce hydrostatic pressures as low as the minimum sea-level pressures of the most intense tropical cyclones. Thus, much of the tropical oceans contain enough moist enthalpy to support a major hurricane.

Throughout most of the Trade Wind regions, gradual subsidence causes an inversion that traps water vapor in the lowest kilometer. Sporadic convection (often in squall lines) that breaks through the inversion exhausts the moist enthalpy stored in the near-surface boundary layer quickly, leaving a wake of cool, relatively dry air. This air comes from just above the inversion and is brought to the surface by downdrafts driven by the weight of hydrometeors and cooling due to their evaporation. If the squall line does not keep moving it quickly runs out of energy. A day, or even several days, may pass before normal fair-weather evaporation can restore the preexistent moist enthalpy behind the squall. The reasons why squall line convection generally fails to produce hurricanes lie in the limited amount of enthalpy that can be stored in the sub-inversion layer and the slow rate of evaporation under normal wind speeds in the trades.

For a tropical cyclone to occur, evaporation must speed up and the equilibrium enthalpy at the sea surface temperature must rise through a lowering of the surface pressure. Tropical cyclones are thus finite-amplitude phenomena. They do not grow by some linear process from infinitesimal amplitude. The normal paradigm of searching for the most rapidly growing unstable linear mode used to study midlatitude cyclogenesis through baroclinic instability fails here. The surface wind has to exceed roughly 20 m s⁻¹ before evaporation can prevail against downdraft cooling.

How then do tropical cyclones reach the required finite amplitude? The answer seems to lie in the structure of tropical convection. As explained previously, behind a squall line the lower troposphere (below the 0 °C isotherm at ~5 km) is dominated by precipitation-driven downdrafts which lie under the ‘anvil’ of nimbostratus and cirrostratus that spreads behind the active convection. Above 5 km, a combination of differential radiative fluxes at the top and bottom of the anvil and residual condensational heating from the main updraft maintains weak rising motion. This updrafts-over-downdrafts arrangement requires horizontal convergence centered near 5 km altitude to maintain mass continuity. The important kinematic consequence is formation of patchy shallow vortices near the altitude of the 0 °C isotherm. The typical horizontal scales of these ‘mesovortices’ are tens to hundreds of kilometers. If they were at the surface or if their influence could be extended downward to the surface then they would be the means to get the system to the required finite amplitude.

The foregoing reasoning defines the important unanswered questions: (1) how do the midlevel mesovortices extend their influence to the surface, and (2) what are the detailed thermodynamics at the air–sea interface during this process? Leading hypotheses for (1) are related to processes that can increase the surface vorticity through changes in static stability and momentum mixing, both horizontally and vertically. However, the answers to these questions await new measurements that are just becoming available through improved observational tools.

Basic Structure

Primary and Secondary Circulations

Inner core dynamics have received a lot of attention over the last 40 years through aircraft observations of the inner core structure. These observations show that the tropical cyclone inner core dynamics are dominated by interactions between ‘primary’ (horizontal axisymmetric), ‘secondary’ (radial and vertical) circulations, and a wavenumber one asymmetry caused by the storm motion. The primary circulation is so strong in the cyclone core that it is possible to consider axisymmetric motions separately, if account is taken of forcing by the asymmetric motions. The primary circulation is in near-gradient balance, and evolves when heat and angular momentum sources (often due to asymmetric motions) force secondary circulations, which in turn redistribute heat and angular momentum.

Figure 6 shows that the primary circulation is sustained by the secondary circulation that consists of frictional inflow that loses angular momentum to the sea as it gains moist enthalpy. (Angular momentum $M = Vr + fr^2/2$, where V is the tangential wind velocity, f the Coriolis parameter, and r the radius from the storm center.) The inflow picks up latent heat through evaporation, and exchanges sensible heat with the underlying ocean, as it spirals into lower levels of the storm under influence of friction. The evaporation of sea spray adds moisture to the air, while at the same time cooling it. This process is important in determining the intensity of a tropical cyclone. Near the vortex center, the inflow turns upward and brings the latent heat it acquires in the boundary layer into the free atmosphere. Across the top of the boundary layer, turbulent eddies cause significant downward flux of sensible heat from the free atmosphere to the boundary layer. The energy source for the turbulent eddies is mechanical mixing caused by the strong winds. The eddies are also responsible for downward mixing of angular momentum. Hence, these turbulent eddy fluxes fuel the storm.

As the air converges towards the eye and is lifted in convective clouds that surround the clear eye, it ascends to the tropopause (the top of troposphere, where temperature stops

decreasing with height). As shown in Figure 6, the convective updrafts in the eyewall turn the latent heat into sensible heat through the latent heat of condensation to provide the buoyancy needed to loft air from the surface to tropopause level. The updraft entrains midlevel air, promoting mass and angular momentum convergence into the core. It is the midlevel inflow that supplies the excess angular momentum needed to spin up the vortex. The thermodynamics of a storm can be modeled as an idealized heat engine, running between a warm heat reservoir, the sea, at around 300 K, and a cold reservoir, 15–18 km up in the tropical troposphere, at about 200 K. The net energy realized in the whole process is proportional to the difference in temperature between the ocean and the upper troposphere. Storm-induced upwelling of cooler water reduces ocean SST by a few degrees, which has a considerable effect on the storm’s intensity.

As shown in Figure 7, the secondary circulation also controls the distribution of hydrometeors and radar reflectivity. It is much weaker than the primary circulation except in the anticyclonic outflow, where the vortex is also much more asymmetric. Precipitation-driven convective updrafts form as hydrometeors fall from the outward sloping updraft. Condensation in the anvil causes a mesoscale updraft above the 0 °C isotherm and precipitation loading by snow falling from the overhanging anvil causes a mesoscale downdraft below 0 °C isotherm. The melting level itself marks the height of maximum mass convergence. Inside the eye, dynamically driven descent and momentum mixing leads to substantial pressure falls.

In order for the primary circulation to intensify, the flow cannot be in exact balance. Vertical gradients of angular momentum due to vertical shears of the primary circulation cause updrafts to pass through the convective heat sources, because the path of least resistance for the warmed air lies along constant angular momentum surfaces. Similarly, horizontal temperature gradients due to vertical shears cause the horizontal flow to pass through momentum sources, because the path of least resistance lies along isentropes (potential temperature or θ surfaces). Although the flow lies generally along the angular

momentum or isentropic surfaces, it has a small component across them. The advection by this component, not the direct forcing, is the mechanism by which the primary circulation evolves.

Some of the most intense tropical cyclones exhibit ‘concentric’ eyewalls, i.e., two or more eyewall structures centered at the circulation center of the storm. In much the same way as the

inner eyewall forms, convection surrounding the eyewall can become organized into distinct rings. Eventually, the inner eye begins to feel the effects of the subsidence resulting from the outer eyewall, and the inner eyewall weakens, to be replaced by the outer eyewall. The pressure rises due to the destruction of the inner eyewall are usually more rapid than the pressure falls, due to the intensification of the outer eyewall, and the cyclone itself weakens for a short period of time. This mechanism, referred to as the eyewall replacement cycle, often accompanies dramatic changes in storm intensity. The intensity changes are often associated with the development of secondary wind maxima outside the storm core.

A good example of contracting rings of convection effecting the intensification of a hurricane is shown in **Figure 8** for Hurricane Gilbert on 14 September 1988. Two convective rings, denoted by intense radar reflectivity, are evident in **Figure 8(a)**. The outer ring is located near 80–90 km radius and the inner one at 10–12 km radius. **Figure 8(b)** shows that both are associated with maxima in tangential wind and vorticity. **Figure 9** shows that in the ensuing 12–24 h the storm filled

dramatically. However, it is not clear how much of the filling was caused by the storm moving over land and how much by the contracting outer ring and decaying inner ring of convective activity.

A process has been proposed whereby: (1) nonlinear balanced adjustment of the vortex to eddy heat and angular momentum sources generated by some environmental interaction in the storm's periphery produces an enhanced secondary circulation; (2) a secondary wind maximum develops in response; and (3) the wind maximum contracts as a result of differential adiabatic warming associated with the convective diabatic heating in the presence of an inward radial gradient of inertial stability. Under these circumstances, understanding the intensification of the tropical cyclone

reduces to determining what mechanisms can produce an enhanced secondary wind maximum.

Inner core – eyewall and eye

The most recognizable feature found within a hurricane is the eye (**Figure 10**). It is found at the center and is typically between 20–50 km in diameter. The eye is the focus of the hurricane, the point about which the primary circulation rotates and where the lowest surface pressures are found in the storm. The eye is a roughly circular area of comparatively light winds and fair weather found at the center of strong tropical cyclones. Although the winds are calm at the axis of rotation, strong winds may extend well into the eye. As seen in **Figure 10**, there is little or no precipitation and sometimes blue sky or stars can be seen. The eye is the region of warmest temperatures aloft – the eye temperature may be $\geq 10^{\circ}\text{C}$ warmer at an altitude of 12 km than the surrounding environment, but only $0\text{--}2^{\circ}\text{C}$ warmer at the surface.

The eye is surrounded by the eyewall, the roughly circular area of deep convection associated with the up-branch of the secondary circulation and the highest surface winds. The eye is composed of air that is slowly sinking and the eyewall has a net upward flow because of many moderate – occasionally strong – updrafts and downdrafts. The eye's warm temperatures are due to warming by compression of the subsiding air. Most soundings taken within the eye are similar to that for Hurricane Hugo in **Figure 11**. They show a low-level layer which is relatively moist, with an inversion above, suggesting that the sinking in the eye typically does not reach the ocean surface, but instead gets only within 1–3 km of the surface. An eye is usually present only in hurricane-strength tropical cyclones.

The general mechanisms by which the eye and eyewall are formed are not fully understood, although observations shed some light on the problem. The calm eye of the tropical

cyclone shares many qualitative characteristics with other vortical systems such as tornadoes, waterspouts, dust devils, and whirlpools. Given that many of these lack a change of phase of water (i.e., no clouds and diabatic heating are involved), it may be that the eye feature is a fundamental component to all rotating fluids. It has been hypothesized that supergradient wind flow (i.e., swirling winds generating stronger centrifugal ‘force’ than the local pressure gradient can support) present near the radius of maximum winds causes air to be centrifuged out of the eye into the eyewall, thus accounting for the subsidence in the eye. However, others found that the swirling winds within several tropical cyclones were within 1–4% of gradient balance. It may be thought that the amount of supergradient flow needed to cause such centrifuging of air is only on the order of a couple of percent and thus difficult to measure.

Another feature of tropical cyclones that probably plays a role in forming and maintaining the eye is the eyewall convection. As shown in Figure 12, convection in developing tropical cyclones is organized into long, narrow rainbands that are oriented in the same direction as the horizontal wind. Because these bands seem to spiral into the center of a tropical cyclone, they are sometimes called spiral bands. The earliest radar observations of tropical cyclones detected these bands, which are typically 5–50 km wide and 100–300 km long. Along these bands, low-level convergence is a maximum, and therefore upper-level divergence is most pronounced. A direct circulation develops in which warm, moist air converges at the surface, ascends through these bands, diverges aloft, and descends on both sides of the bands. Subsidence is distributed over a wide

area outside of the rainband, but is concentrated in the small inside area. As the air subsides, adiabatic warming takes place, and the air dries. Because subsidence is often concentrated on the inside of the band, the adiabatic warming is stronger inward from the band, causing a sharp contrast in pressure falls across the band since warm air is lighter than cold air. Because of the pressure falls on the inside, the tangential winds around the tropical cyclone increase, owing to an increased pressure gradient. Eventually, the band moves toward the center and encircles it and the eye and eyewall form.

The circulation in the eye is comparatively weak and, at least in the mature stage, thermally indirect (warm air descending), so it cannot play a direct role in the storm energy production. On the other hand, the temperature in the eye of many hurricanes exceeds that which can be attained by any conceivable moist adiabatic ascent from the sea surface, even accounting for the additional entropy (positive potential temperature, θ , anomaly) owing to the low surface pressure in the eye (the lower the pressure, the higher the θ at a given altitude and temperature). Thus, the observed low central pressure of the storm is not consistent with that calculated hydrostatically from the temperature distribution created when a sample of air is lifted from a state of saturation at sea surface temperature and pressure. The thermal wind balance restricts the amount of warming that can take place. In essence, the rotation of the eye at each level is imparted by the eyewall, and the pressure drop from the outer to the inner edge of the eye is simply that required by gradient balance.

Because the eyewall azimuthal velocity decreases with height, the radial pressure drop decreases with altitude, requiring,

Figure 12 (a) Schematic of the rainband in radius–height coordinates. Reflectivity, θ_e , mesoscale (arrows), and convective scale motions are shown. (b) Plan view. Aircraft track, reflectivities, cells, stratiform precipitation, 150 m flow, and θ_e values are shown. Reproduced with permission from Barnes GM, Zipser EJ, Jorgensen DP, and Marks FD (1983) Mesoscale and convective structure of a hurricane rainband. *Journal of the Atmospheric Sciences* 40: 2125–2137; © American Meteorological Society.

through the hydrostatic equation, a temperature maximum at the storm center. Thus, given the swirling velocity of the eyewall, the steady-state eye structure is largely determined. The central pressure, which is estimated by integrating the gradient balance equation inward from the radius of maximum winds, depends on the assumed radial profile of azimuthal wind in the eye.

In contrast, the eyewall is a region of rapid variation of thermodynamic variables. As shown in Figure 13, the transition from the eyewall cloud to the nearly cloud-free eye is often so abrupt that it has been described as a form of atmospheric front. Early studies were the first to recognize that the flow under the eyewall cloud is inherently frontogenetic. The eyewall is the upward branch of the secondary circulation and a region of rapid ascent that, together with slantwise convection, leads to the congruence of angular momentum and moist entropy (θ_e) surfaces. Hence, the three-dimensional vorticity vectors lie on θ_e surfaces, so that the moist PV vanishes. As the air is saturated, this in turn implies, through the invertibility principle applied to flow in gradient and hydrostatic balance, that the entire primary circulation may be deduced from the radial distribution of θ_e in the boundary layer and the distribution of vorticity at the tropopause.

In the classic semigeostrophic theory of deformation-induced frontogenesis, the background geostrophic deformation flow provides the advection of temperature across surfaces of absolute momentum that drives the frontogenesis, whereas in the hurricane eyewall, surface friction provides the radial advection of entropy across angular momentum surfaces. Also note that the hurricane eyewall is not necessarily a front in surface temperature, but instead involves the θ_e distribution, which is related directly to density in saturated air.

There is likely a two-stage process in eye formation. The amplification of the primary circulation is strongly frontogenetic and results, in a comparatively short time, in frontal collapse at the inner edge of the eyewall. (Frontal collapse is an increase in the horizontal gradient of an airmass property, principally density, and the development of the accompanying features of the wind field through the secondary circulation that typify a front.) The frontal collapse leads to a dramatic transition in the storm dynamics. While the tropical cyclone inner core is dominated by axisymmetric motions, hydrodynamic instabilities are potential sources of asymmetric motions within the

Figure 13 Time series plots of tangential wind (V_θ), radial wind (V_r), vertical velocity (w), and θ_e in Hurricane Hugo at 1721–1730 UTC, 15 September 1989. The aircraft flight track was at 450 m. Thick dashed vertical lines denote the width of the eyewall reflectivity maximum at low levels.

core. In intense tropical cyclones the wind profile inside the eye is often U-shaped, in the sense that the wind increases outwards more rapidly than linearly with radius (Figure 13). The strong cyclonic shear just inside the eyewall may result in a local maximum of absolute vorticity or angular momentum, so that the profile may actually become barotropically unstable. (This refers to the hydrodynamic instability arising from certain distributions of vorticity in a two-dimensional nondivergent flow. It is an inertial instability in that kinetic energy is the only form of energy transferred between the current and perturbation. A well-known necessary condition for barotropic instability is that the basic state vorticity gradient must have both signs in the domain of interest.) This instability leads to frontal collapse as a result of radial diffusion of momentum into the eye, and also may explain the ‘polygonal eyewalls’ where the eyewall appear on radar to be made up of a series of line segments rather than as a circle. It may also explain intense mesoscale vortices observed in the eyewalls of Hurricanes Hugo of 1989 and Andrew of 1992.

Once the radial turbulent diffusion of momentum driven by the instability of the primary circulation becomes important, it results in a mechanically induced, thermally indirect (warm air sinking) component of the secondary circulation in the eye and eyewall. Such a circulation raises the vertically averaged temperature of the eye beyond its value in the eyewall and allows for an amplification of the entropy distribution. Feedbacks with the surface fluxes then allow the boundary layer entropy to increase and result in a more rapid intensification of the swirling wind. Thus, the frontal collapse of the eyewall is an essential process in the evolution of tropical cyclones. Without it, amplification of the temperature distribution relies on external influences, and intensification of the wind field is slow. Once it has taken place, the mechanical spinup of the eye allows the temperature distribution to amplify without external influences and, through positive feedback with surface fluxes, allows the entropy field to amplify and the swirling velocity to increase somewhat more rapidly.

Outer structure and rainbands

The axisymmetric core is characteristically surrounded by a less symmetric outer vortex that diminishes into the synoptic ‘environment’. In the lower troposphere, the cyclonic circulation may extend more than 1000 km from the center. As evident in Figure 14 the boundary between cyclonic and anticyclonic circulation slopes inward with increasing height, so that the circulation in the upper troposphere is primarily anticyclonic, except near the core. In the outer vortex, there are no scale separations between the primary and the secondary circulations, the asymmetric motions, or the vortex translation, as they are roughly all of the same magnitude. The asymmetric flows in this region control the vortex motion and sustain an eddy convergence of angular momentum and moisture toward the center. Interactions between the symmetric motions of the inner core with the more asymmetric motions in the outer portion of the storm are the key to improved forecasts of tropical cyclone track and intensity.

Spiral bands of precipitation characterize radar and satellite images in this region of the storm (Figure 1 and Figure 15). As seen in Figure 8, Figure 12 and Figure 15, radar reflectivity

patterns in tropical cyclones provide a good means for flow visualization, although they represent precipitation, not winds. Descending motion occupies precipitation-free areas, such as the eye. The axis of the cyclone's rotation lies near the center of the eye. The eyewall surrounds the eye. In intense hurricanes, it may contain reflectivities as high as 50 dBZ equivalent to rainfall rates of 74 mm h^{-1} . (1 dBZ $10 \lg Z$, where Z is equivalent radar reflectivity factor ($\text{mm}^6 \text{ m}^{-3}$).) Less extreme reflectivities, 40 dBZ (13 mm h^{-1}), characterize most convective rainfall in the eyewall and spiral bands. The vertical velocities (both up and downdrafts) in convection with highest reflectivity may reach 25 m s^{-1} , but typical vertical velocities are $<5 \text{ m s}^{-1}$. Such intense convection occupies less than 10% of the tropical cyclone's area. Outside convection, reflectivities are still weaker, 30 dBZ, equivalent to a 2.4 mm h^{-1} rain rate. This 'stratiform rain', denoted by a distinct reflectivity maximum or 'bright band' at the altitude of the 0°C isotherm, falls out of the anvil cloud that grows from the convection. The spiral bands tend to lie along the friction-layer wind that spirals inward toward the eyewall (Figure 12).

Many aspects of rainband formation, dynamics, and interaction with the symmetric vortex are still unresolved. The trailing spiral shape of bands and lanes arises because the angular velocity of the vortex increases inward and deforms them into equiangular spirals. In the vortex core, air remains in the circulation for many orbits of the center, while outside the core, the air passes through the circulation in less than the time required for a single orbit. As the tropical cyclone becomes more intense, the inward ends of the bands approach the center less steeply approximating arcs of circles. Some bands appear to move outward, while others maintain a fixed location relative to the translating center.

As shown in Figure 15, motion of the vortex through its surroundings may cause one stationary band, called the principal band, to lay along a convergent streamline asymptote that spirals into the core. A tropical cyclone advected by midlevel steering with westerly shear moves eastward through surrounding air at low levels. Thus, the principal band may be like a bow wave, caused by the displacement of the environmental air on the eastern side of the vortex. Its predominant azimuthal wavenumber is one.

Moving bands, and other convective features, are frequently associated with cycloidal motion of the tropical cyclone center, and intense asymmetric outbursts of convection are observed to displace the tropical cyclone center by tens of kilometers. The bands observed by radar are often considered manifestations of internal gravity waves, but these waves can exist only in a band of Doppler-shifted frequencies between the local inertia frequency (defined as the sum of the vertical component of the earth's inertial frequency, f , and the local angular velocity of the circulation, V/r) and the Brunt-Väisälä frequency (i.e., the natural gravity wave frequency, the square root of the static stability defined as $(g/\theta) \partial\theta/\partial z$). Only two classes of trailing-spiral, gravity wave solutions lie within this frequency band: (1) waves with any tangential wavenumber that move faster than the swirling wind, and (2) waves with tangential wavenumber ≥ 2 that move slower than the swirling wind.

Bands moving faster than the swirling wind with outward phase propagation are observed by radar. They are more like squall lines than linear gravity waves. Waves moving slower

than the swirling wind propagate wave energy and anticyclonic angular momentum inward, grow at the expense of the mean-flow kinetic energy, and reach appreciable amplitude if they are excited at the periphery of the tropical cyclone. Alternate explanations for these inward-propagating bands involve filamentation of vorticity from the tropical cyclone environment, asymmetries in the radially shearing flow of the vortex, and high-order vortex Rossby waves. Detailed observations of the vortex-scale rainband structure and windfield are necessary to determine which mechanisms play a role in rainband development and maintenance.

While the evolution of the inner core is dominated by interactions between the primary, secondary, and track-induced wavenumber-one circulation, there is some indication that the local convective circulations in the rainbands may impact on intensity change. Although precipitation in some bands is largely stratiform, condensation in most bands tends to be concentrated in convective cells rather than spread over wide mesoscale areas. As shown in Figure 12, convective elements form, move through the bands, and dissipate as they move downwind. Doppler radar observations indicate that the roots of the updrafts lie in convergence between the low-level radial inflow and gust fronts produced by convective downdrafts. This convergence may occur on either side of the band. A 20 K decrease in low-level θ_e was observed in a rainband downdraft, suggesting that the draft acts as a barrier to inflow. This reduction in boundary layer energy may be advected near the center, inhibit convection, and thereby alter storm intensity.

Motion

Tropical cyclone motion is the result of a complex interaction between a number of internal and external influences. Environmental steering is typically the most prominent external influence on a tropical cyclone, accounting for as much as 70–90% of the motion. Theoretical studies show that in the absence of environmental steering, tropical cyclones move poleward and westward owing to internal influences.

Accurate determination of tropical cyclone motion requires accurate representation of interactions that occur throughout the depth of the troposphere on a variety of scales. Observations spurred improved understanding of how tropical cyclones move using simple barotropic and more complex baroclinic models. To first order, the storm moves with some layer average of the lower-tropospheric environmental flow: the translation of the vortex is roughly equal to the speed and direction of the basic 'steering' current. However, the observations show that tropical cyclone tracks deviate from this simple steering flow concept in a subtle and important manner. Several physical processes may cause such deviations. The approach in theoretical and modeling of tropical cyclones has been to isolate each process in a systematic manner to understand the magnitude and direction of the track deviation caused by each effect. The β effect opposes the advection of relative vorticity through the differential advection of the Earth's vorticity, f , that slows the advection of the disturbance. (The β effect is the asymmetric vorticity advection around the vortex caused by the latitudinal gradient of f ; $\beta = 2\Omega \cos \phi$. β has a maximum value at the Equator (i.e., $2.289 \times 10^{-11} \text{ s}^{-1}$)

and becomes zero at the pole.) Models that are more complete describe not only the movement of the vortex but also the accompanying wavenumber-one asymmetries that develop owing to the differential advection of f on the east and west side of the vortex. It was also discovered that the role of meridional and zonal gradients of the environmental flow could add greatly to the complexity even in the barotropic evolution of a vortex. Hence, the evolution of the movement depends on not only the relative vorticity gradient and on shear of the environment but also the structure of the vortex itself.

Generally, the propagation vector of these model baroclinic vortices is very close to that expected from a barotropic model initialized with the vertically integrated environmental wind. An essential feature in baroclinic systems is the relative vorticity advection through the storm center, where the vertical structure of the tropical cyclone produces a tendency for the low-level vortex to move slower than the simple propagation of the vortex due to β . Vertical shear plays an important factor in determining what the relative flow is, though there is no unique relation between the shear and storm motion. Diabatic heating effects also alter this flow and change the propagation velocity. Thus, tropical cyclone motion is primarily governed by the dynamics of the low-level cyclonic circulation; however, the addition of observations of the upper-level structure may alter this finding.

Interaction with the Atmospheric Environment

A consensus exists that small vertical shear of the environmental wind and lateral eddy imports of angular momentum are favorable to tropical cyclone intensification. The inhibiting effect of vertical shear in the environment on tropical cyclone intensification is well known from climatology and forecasting experience. Exposure of the low-level circulation from under the tropical cyclones large area of cirrus (central dense overcast) in satellite imagery is universally recognized as a symptom of shear, and as an indication of a nonintensification or weakening. Nevertheless, the detailed dynamics of a vortex in shear has been the topic of surprisingly little study, probably because while the effect is a reliable basis for practical forecasting, it is difficult to measure and model.

In contrast, the positive effect of eddy momentum imports at upper levels has received extensive study. Modeling studies with composite initial conditions show that eddy momentum fluxes can intensify a tropical cyclone even when other conditions are neutral or unfavorable. It has been shown theoretically that momentum imports can form a tropical cyclone in an atmosphere with no buoyancy. Statistical analysis of tropical cyclones reveals a clear relationship between angular momentum convergence and intensification, but only after the effects of shear and SST variations are accounted for. Such interactions occur frequently (35% of the time, defined by eddy angular momentum flux convergence exceeding $10 \text{ m s}^{-1} \text{ day}^{-1}$), and likely represent the more common upper-boundary interaction for tropical cyclones. Frequently they are accompanied by eyewall cycles and dramatic intensity changes.

The environmental flows that favor intensification, and presumably inward eddy momentum fluxes, usually involve interaction with a synoptic-scale cyclonic feature, such as a midlatitude upper-level trough or PV anomaly. Given the

interaction of an upper-level trough and the tropical cyclone, the exact mechanism for intensification is still uncertain. The secondary circulation response to momentum and heat sources is very different. Upper-tropospheric momentum sources can influence the core directly. As can be seen in Figure 16, large inertial stability in the lower troposphere protects the mature tropical cyclone core from direct influence by momentum sources (inertial stability is a measure of the resistance to horizontal displacements, based on the conservation of angular momentum for a vortex in gradient balance, and is defined as $(f + \zeta)(f + V^2/r)$, where ζ is the relative vorticity, V the axial wind velocity, f the Coriolis parameter, and r the radius from the storm center); however, the inertial stability in the upper troposphere is smaller and a momentum source can induce an outflow jet with large radial extent just below the tropopause. If the eyewall updraft links to the direct circulation at the entrance region of the jet, as shown in Figure 17(c) and 17(d), the exhaust outflow is unrestricted. The important difference between heat and momentum sources is that the roots of the diabatically induced updraft must be in the inertially stiff lower troposphere, but the outflow jet due to a momentum-flux convergence can be confined to the inertially stable upper troposphere. Momentum forcing does not spin the vortex up directly. It makes the exhaust flow stronger and reduces local compensating subsidence in the core, thus cooling the upper troposphere and destabilizing the sounding. The cooler upper troposphere leads to less thermal-wind shear and a weaker upper anticyclone.

A two-dimensional balanced approach provides reasonable insight into the nature of the tropical cyclone intensification as a trough approaches. Isentropic PV analysis (Figure 17)), which express the problem in terms of a quasi-conserved variable in three dimensions, are used to describe various processes in

Figure 16 Axisymmetric mean inertial stability for Hurricane Gloria on 24 September 1985. Contours are shown as multiples of f^2 at the latitude of Gloria's center. idealized tropical cyclones with considerable success. The eddy heat and angular momentum fluxes are related to changes in the isentropic PV through their contribution to the eddy flux of PV.

It has been suggested that outflow-layer asymmetries, as in [Figure 17](#), and their associated circulations could create a mid- or lower-tropospheric PV maximum outside the storm core, either by creating breaking PV waves on the mid-tropospheric radial PV gradient ([Figure 3](#)) or by diabatic heating. It has been shown that filamentation of any such PV maximum in the ‘surf zone’ outside the tropical cyclone core (the sharp radial PV gradient near 100 km radius) produces a feature much like a secondary wind maximum, which was apparent in the PV

fields of Hurricane Gloria in [Figure 3](#). These studies thus provide mechanisms by which outflow-layer asymmetries could bring about a secondary wind maximum.

An alternative argument has been proposed for storm reintensification as a ‘constructive interference without phase locking’, as shown in [Figure 18](#). As the PV anomalies come within the Rossby radius of deformation, the pressure and wind perturbations associated with the combined anomalies are greater than when the anomalies are apart, even though the PV magnitudes are unchanged. The perturbation energy comes from the basic-state shear that brought the anomalies together. However, constructive interference without some additional

Figure 18 Cross-sections of potential vorticity from north-west (left) to south-east (right) through the observed center of Hurricane Elena at the same times as in Figure 17, plus (A) at 0000 UTC 30 August and (F) 1200 UTC 1 September. Increment is 0.5 PVU and shading above 1 PVU. Reproduced with permission from Molinari J, Skubis S, and Vollaro D (1995) External influences on hurricane intensity. 3. Potential vorticity structure. *Journal of the Atmospheric Sciences* 52: 3593–3606; © American Meteorological Society.

diabatic component cannot account for intensification. It is possible that intensification represents a baroclinic initiation of a wind-induced surface heat exchange. By this mechanism, the constructive interference induces stronger surface wind anomalies, which produce larger surface moisture fluxes and thus higher surface moist enthalpy. This feeds back through the associated convective heating to produce a stronger secondary circulation and thus stronger surface winds. The small effective static stability in the saturated, nearly moist neutral storm core ensures a deep response, so that even a rather narrow upper trough can initiate this feedback process. The key to this mechanism is the direct influence of the constructive interference on the surface wind field, as that controls the surface flux of moist enthalpy.

Interaction with the Ocean

As pointed out in the climatology section, preexisting SSTs $>26^{\circ}\text{C}$ are a necessary but insufficient condition for tropical cyclogenesis. Once the tropical cyclone develops and translates over the tropical oceans, statistical models suggest that warm SSTs describe a large fraction of the variance (40–70%) associated with the intensification phase of the storm. However, these predictive models do not account either for the oceanic mixed layers having temperatures of $0.5\text{--}1^{\circ}\text{C}$ cooler than the relatively thin SST over the upper meter of the ocean or horizontal advective tendencies by basic-state ocean currents such as the Gulf Stream and warm core eddies. Thin layers of warm SST are well mixed with the underlying cooler mixed layer water well in advance of the storm where winds are a few meters per second, reducing SST as the storm approaches. However, strong oceanic baroclinic features advecting deep, warm oceanic mixed layers represent moving reservoirs of high-heat-content water available for the continued development and intensification phases of the tropical cyclone. Beyond a first-order description of the lower boundary providing the heat and moisture fluxes derived from low-level convergence, little is known about the complex boundary layer interactions between the two geophysical fluids.

One of the more apparent aspects of the atmospheric–oceanic interactions during tropical cyclone passage is the upper-ocean cooling as manifested in the SST (and mixed-layer temperature) decrease starting just in back of the eye. As seen in Figure 19, ocean mixed-layer temperature profiles acquired during the passage of several tropical cyclones revealed a crescent-shaped pattern of upper-ocean cooling and mixed-layer depth changes, which indicated a rightward bias in the mixed-layer temperature response with cooling by $1\text{--}5^{\circ}\text{C}$ extending from the right rear quadrant of the storm into the wake regime. These SST decreases are observed through satellite-derived SST images, such as that of the post-Hurricane Bonnie SST (Figure 20), which are indicative of mixed-layer depth changes due to stress-induced turbulent mixing in the front of the storm and shear-induced mixing between the layer and thermocline in the rear half of the storm. The mixed-layer cooling represents the thermodynamic and dynamic response to the strong wind that typically accounts for 75–85% of the ocean heat loss, compared with the 15–25% caused by surface latent and sensible heat fluxes from the ocean to the atmosphere. Thus, the upper ocean's heat content for tropical

Figure 19 Schematic SST change ($^{\circ}\text{C}$) induced by a hurricane. The distance scale is indicated in multiples of the radius of maximum wind. Storm motion is to the left. The horizontal dashed line is at 1.5 times the radius of maximum wind. cyclones is governed not solely by SST; rather, it is the mixed-layer depths and temperatures that are significantly affected along the lower boundary by the basic state and transient currents.

Recent observational data have shown that the horizontal advection of temperature gradients by basic state currents in a warm core ring affected the mixed-layer heat and mass balance, suggesting the importance of these warm oceanic baroclinic features. In addition to enhanced air–sea fluxes, warm temperatures ($>26^{\circ}\text{C}$) may extend to 80–100 m in warm core rings, significantly impacting the mixed-layer heat and momentum balance. That is, strong current regimes ($1\text{--}2\text{ m s}^{-1}$) advecting deep, warm upper-ocean layers not only represent deep reservoirs of high-heat-content water with an upward heat flux, but transport heat from the tropics to the subtropical and polar regions as part of the annual cycle. Thus, the basic state of the mixed layer and the subsequent response represent an evolving three-dimensional process with surface fluxes, vertical shear across the entrainment zone, and horizontal advection. Simultaneous observations in both fluids are lacking over these baroclinic features prior, during, and subsequent to tropical cyclone passage, and are crucially needed to improve our understanding of the role of lower boundary in intensity and structural changes to intensity change.

In addition, wave height measurements and current profiles revealed the highest waves and largest fetches to the right side of the storm where the maximum mixed-layer changes occurred. Mean wave-induced currents were in the same direction as the steady mixed-layer currents, modulating vertical current shears and mixed-layer turbulence. These processes feed back to the atmospheric boundary layer by altering the surface roughness and hence the drag coefficient. However, little is known about the role of strong surface waves on the mixed-layer dynamics, and their feedback to the atmospheric boundary layer under tropical cyclone force winds by altering the drag coefficient.

Figure 20 Cold wake produced by Hurricane Bonnie for 24–26 August 1998, as seen by the NASA TRMM satellite Microwave Imager (TMI). Small white patches are areas of persistent rain over the 3-day period. White dots show Hurricane Bonnie's daily position from 24 to 26 August. Gray dots show the later passage of Hurricane Danielle from 27 August to 1 September. Danielle crossed Bonnie's wake on 29 August and its intensity dropped. Tropical Cyclone Rainfall

Precipitation in tropical cyclones can be separated into either convective or stratiform regimes. Convective precipitation occurs primarily in the eyewall and rainbands, producing rains $>25 \text{ mm h}^{-1}$ over small areas. However, observations suggest that only 10% of the total rain area is comprised of these convective rain cores. The average core is 4 km in radius (area of 50 km^2), and has a relatively short lifetime, with only 10% lasting longer than 8 min (roughly the time a 1 mm diameter raindrop takes to fall from the mean height of the 0°C isotherm at terminal velocity). The short life cycle of the cores and the strong horizontal advection produce a well-mixed and less asymmetric precipitation pattern in time and space. Thus, over 24 h the inner core of a tropical cyclone as a whole produces 1–2 cm of precipitation over a relatively large area, and 10–20 cm in the core. After landfall, orographic forcing can anchor heavy precipitation to a local area for an extended time. Additionally, midlatitude interaction with a front or upper-level trough can enhance precipitation, producing a distortion of the typical azimuthally uniform precipitation distribution.

Energetics

Energetically, a tropical cyclone can be thought of, to a first approximation, as a heat engine; obtaining its heat input from the warm, humid air over the tropical ocean, and

releasing this heat through the condensation of water vapor into water droplets in deep thunderstorms of the eyewall and rainbands, then giving off a cold exhaust in the upper levels of the troposphere ($\sim 12 \text{ km}$ up). One can look at the energetics of a tropical cyclone in two ways: (1) the total amount of energy released by the condensation of water droplets or (2) the amount of kinetic energy generated to maintain the strong swirling winds of the hurricane. It turns out that the vast majority of the heat released in the condensation process is used to cause rising motions in the convection, and only a small portion drives the storm's horizontal winds.

Using the first approach, we assume an average tropical cyclone produces 1.5 cm day^{-1} of rain inside a circle of radius 665 km. Converting this to a volume of rain gives $2.1 \times 10^{16} \text{ cm}^3 \text{ day}^{-1}$ (1 cm^3 of rain weighs 1 g). The energy released through the latent heat of condensation to produce this amount of rain is $5.2 \times 10^{19} \text{ J day}^{-1}$ or $6.0 \times 10^{14} \text{ W}$, which is equivalent to 200 times the worldwide electrical generating capacity.

Under the second approach we assume that for a mature hurricane, the amount of kinetic energy generated is equal to that being dissipated due to friction. The dissipation rate per unit area is air density times the drag coefficient times the wind speed cubed. Assuming an average wind speed for the inner core of the hurricane of 40 m s^{-1} winds over a 60-km radius, the wind dissipation rate (wind generation rate) would be $1.5 \times 10^{12} \text{ W}$. This is

equivalent to about half the worldwide electrical generating capacity.

Either method suggests hurricanes generate an enormous amount of energy. However, they also imply that only about 2.5% of the energy released in a hurricane by latent heat released in clouds actually goes to maintaining the hurricane's spiraling winds.

Tropical Cyclone-Related Hazards

In the coastal zone, extensive damage and loss of life are caused by the storm surge (a rapid, local rise in sea level associated with storm landfall), heavy rains, strong winds, and tropical cyclone-spawned severe weather (e.g., tornadoes). The continental United States currently averages nearly \$5 billion (in 1998 dollars) annually in tropical-cyclone-caused damage, and this is increasing, owing to growing population and wealth in the vulnerable coastal zones.

Before 1970, large loss of life stemmed mostly from storm surges. The height of storm surges varies from 1 to 2 m in weak systems to more than 6 m in major hurricanes that strike coastlines with shallow water offshore. The storm surge associated with Hurricane Andrew (1992) reached a height of about 5 m, the highest level recorded in south-east Florida. Hurricane Hugo's (1989) surge reached a peak height of nearly 6 m about 20 miles north-east of Charleston, South Carolina, and exceeded 3 m over a length of nearly 180 km of coastline. In recent decades, large loss of life due to storm surges in the United States has become less frequent because of improved forecasts, fast and reliable communications, timely evacuations, a better-educated public, and a close working relationship between the National Hurricane Center (NHC), local weather forecast offices, emergency managers, and the media. Luck has also played a role, as there have been comparatively few landfalls of intense storms in populous regions in the last few decades. The rapid growth of coastal populations and the complexity of evacuation raises concerns that another large storm surge disaster might occur along the eastern or Gulf Coast shores of the United States.

In regions with effectively enforced building codes designed for hurricane conditions, wind damage is typically not so lethal as the storm surge, but it affects a much larger area and can lead to large economic loss. For instance, Hurricane Andrew's winds produced over \$25 billion in damage over southern Florida and Louisiana. Tornadoes, although they occur in many hurricanes that strike the United States, generally account for only a small part of the total storm damage.

While tropical cyclones are most hazardous in coastal regions, the weakening, moisture-laden circulation can produce extensive, damaging floods hundreds of miles inland long after the winds have subsided below hurricane strength. In recent decades, many more fatalities in North America have occurred from tropical-cyclone-induced inland flash flooding than from the combination of storm surge and wind. For example, although in 1972 the deaths from storm surge and wind along the Florida coast from Hurricane Agnes were minimal, inland flash flooding caused more than 100 deaths over the north-eastern United States. More recently, rains from Hurricane Mitch in 1998 killed at least 10 000 people in Central America, the majority after the storm had weakened to tropical storm strength. An essential difference in the threat

from flooding rains, compared with that from wind and surge, is that the rain amount is not tied to the strength of the storm's winds. Hence, any tropical disturbance, from depression to major hurricane, is a major rain threat.

Over each ocean basin that experiences tropical cyclones, the poleward movement of a tropical cyclone into the midlatitudes is normally associated with the decay stage of its life cycle. However, these systems can develop into fast-moving and rapidly developing extratropical cyclones that contain tropical cyclone-force winds. These transforming tropical cyclones may accelerate from forward speeds of 5 m s^{-1} in the tropics to $>20 \text{ m s}^{-1}$ in the midlatitudes. They pose a serious threat and forecast problem to maritime activities and shore locations over wide geographic regions that do not normally experience such conditions. A common problem in all these regions is the difficult challenge of predicting accurately the track, intensity, and impacts of these rapidly changing systems after advisories have been discontinued by the tropical cyclone forecast center. Forecasters responsible for producing warnings and advisories during extratropical transition are faced with the potential for large amounts of precipitation, continued high wind speed, and generation of large ocean waves and swell common in tropical cyclones. However, the increased translation speed decreases the warning time. Over land, the impacts are related to the intensity of surface winds and precipitation as in Hurricane Hazel in 1954, which resulted in a rapid intensification and precipitation amounts $>200 \text{ mm}$, leading to 83 deaths in the Toronto area of southern Ontario. Over the open ocean the increased storm motion combined with the continued high wind speeds produces extremely large surface waves, as in Hurricane Luis in 1995, which produced waves $>30 \text{ m}$, causing extensive damage to the luxury liner *Queen Elizabeth II*.

Tropical Cyclone Forecasting

When a tropical cyclone threatens there are four questions that must be answered: (1) where will it hit, (2) when will it hit, (3) how strong will it be, and (4) what type of threat should be expected (i.e., wind, storm surge, heavy rain, severe weather). The answers to these four questions are the goal of tropical cyclone forecasters. Track is the most important forecast, as it determines the answers to the first two questions. Operational tropical cyclone track forecasting is a semiobjective process that combines conventional, satellite, and reconnaissance observations with input from objective prediction models. At 12–24-h forecast intervals, persistence of storm motion is a major component of the forecast. However, an error in the initial motion of 1 m s^{-1} will yield an 84.6 km error in the 24 h forecast position. Since the tropical cyclone motion processes are complex and nonlinear, track uncertainty increases with time. For example, in the United States, where track errors are the lowest globally, the mean 24-h track error over the last 10 years is 170 km. However, 5% of the 24-h track errors over the last 10 years are $>370 \text{ km}$. To minimize the possibility that a coastal area may be struck without time to prepare, much larger areas are warned than will actually experience damaging winds. While specific track models have indicated up to 15% improvement over the past 2–3 years, the average length of coastline warned, 730 km (roughly a 4:1 ratio to the track error) has not decreased over the past decade. In fact, it has increased

over the 30-year mean of 556 km in response to the emergency manager's desire for longer lead time.

In the United States, emergency managers require communities with limited escape routes to complete preparation and evacuation before 17 m s⁻¹ winds arrive on the coast. Hence, the length of coastline warned is a combination of the forecast uncertainty in the track forecast and the uncertainty in the forecast of the radius of the 17 m s⁻¹ winds. The mean 24-h error of the forecast 17 m s⁻¹ wind radii is 71 km, which is about 30–35% of the actual radii, and represents a 4-h error in lead time for a typical storm motion of 5 m s⁻¹. However, 5% of the 17 m s⁻¹ wind radii forecasts exceed 255 km. The warning of 730 km of the coastline is justified as the sum of the 370 km uncertainty in the track forecast plus the 255 km uncertainty in the 17 m s⁻¹ wind radii forecast to be more than 95% confident that a coastal region will not be struck without warning. Such overwarning is costly! Our best estimates of average preparation costs for the warned coastline have increased roughly sixfold from \$50 million in 1989 to \$300 million in 1996 (\$410 000 km⁻¹ warned).

Another factor in the warning equation is storm intensity, which addresses the third question. Preparations differ considerably for a major hurricane or super typhoon than for a lesser storm (e.g., storm surge inundation varies greatly with storm intensity). In the United States the mean 24-h intensity forecast error over the last 10 years is 5 m s⁻¹ (half a category on the Saffir–Simpson scale; Table 1), and 5% of the intensity errors are >12.5 m s⁻¹ (over 1 category on the Saffir–Simpson scale). At 48 h, the mean intensity error is 8 m s⁻¹, and 5% are >20 m s⁻¹ (two categories on the Saffir–Simpson scale). Because the forecast intensity of the storm at landfall is a key factor in who evacuates, greater accuracy can lead to increased public safety and reduced costs, although these savings have yet to be quantified.

Understanding and predicting intensity change is more complex than that for track as it requires knowledge of interactions throughout the depth of the troposphere over a broad spectrum of scales. Observations are sparse in upper troposphere, atmospheric boundary layer, and upper ocean, limiting knowledge of environmental interactions, angular momentum imports, boundary layer stress, and air–sea interactions. Moreover, sea surface temperature remains an important but incomplete measure of the ocean's influence on tropical cyclone intensity change. Crucial unanswered questions concerning tropical cyclone intensity change lie in the relative impact and interactions of three major components: (1) the structure of the upper-ocean circulations that control the oceanic mixed-layer heat content, (2) the storm's inner core dynamics, and (3) the structure of the synoptic-scale upper-tropospheric environment. A successful intensity forecast requires knowledge of the mechanisms that modulate tropical cyclone intensity within the envelope defined by these three components.

Once the 17 m s⁻¹ wind radius crosses the coast the important forecast issues relate to determining how much damage is likely from wind, ensuing surge, rain, and severe weather, the answer to the fourth question. These factors will determine the type and level of emergency management response, and dictate where the most resources for recovery are needed. To a first order, the areas impacted by wind,

ensuing surge, rain, and severe weather are determined by the horizontal and vertical wind distribution in the boundary layer and the interaction of the wind field with coast and inland topography. Currently, only a little information is known about the wind structure and its distribution with height and radial distance near landfall because of the paucity of observations (research quality or otherwise). Hence, a concerted effort is needed to better understand what determines the distribution of wind with height and radial distance in a high-wind boundary layer. As with the intensity forecasts, greater accuracy in the specification of the three-dimensional wind structure at landfall should lead to increased public safety and reduced costs, although these savings have yet to be quantified.

Summary

'The eye of the storm' is a metaphor for calm within chaos. The core of a tropical cyclone, encompassing the eye and the inner 100–200 km of the cyclone's 1000–1500 km radial extent, is hardly tranquil. However, the rotational inertia of the swirling wind makes it a region of orderly, but intense, motion. It is dominated by a cyclonic primary circulation in balance with a nearly axisymmetric, warm-core, low-pressure anomaly. Superimposed on the primary circulation are weaker asymmetric motions and an axisymmetric secondary circulation. The asymmetries modulate precipitation and cloud into trailing spirals. Because of their semibalanced dynamics, the primary and secondary circulations are relatively simple and well understood. These dynamics are not valid in the upper troposphere, where the outflow is comparable to the swirling flow, nor do they apply to the asymmetric motions. Since the synoptic-scale environment appears to interact with the vortex core in the upper troposphere by means of the asymmetric motions, future research should emphasize this aspect of the tropical cyclone dynamics and their influence on the track and intensity of the storm.

Improved track forecasts, particularly the location and time when a tropical cyclone crosses the coast, are achievable with more accurate specification of the initial conditions of the large-scale environment and the tropical cyclone wind fields. Unfortunately, observations are sparse in the upper troposphere, atmospheric boundary layer, and upper ocean, limiting knowledge of environmental interactions, angular momentum imports, boundary layer stress, and air–sea interactions. In addition to the track, an accurate forecast of the storm intensity is needed because it is the primary determinant of localized wind damage, severe weather, storm surge, ocean wave runup, and even precipitation during landfall. A successful intensity forecast requires knowledge of the mechanisms that modulate tropical cyclone intensity through the relative impact and interactions of three major components: (1) the structure of the upper ocean circulations that control the mixed-layer heat content, (2) the storm's inner core dynamics, and (3) the structure of the synoptic-scale upper-tropospheric environment. Even if we could make a good forecast of the landfall position and intensity, our knowledge of how a tropical cyclone's structure changes as it makes landfall is in its infancy, because few hard data survive the harsh condition. To improve

forecasts, developments to improve our understanding through observations, theory, and modeling need to be advanced together.

Tropical Cyclogenesis

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

Tropical cyclogenesis is the least understood phase of the tropical cyclone life cycle. This article provides an overview of the necessary large-scale conditions for tropical cyclone formation, the climatology and seasonality of tropical cyclone formation over different oceanic basins, as well as the theories and predictability of tropical cyclone formation.

Introduction

Tropical cyclones are the most severe storm systems in the tropics. Tropical cyclogenesis, or the formation of a tropical cyclone, is the least understood phase of the tropical cyclone life cycle and one of the great mysteries in tropical meteorology. The challenge can be attributed to the lack of *in situ* observations that capture the genesis processes over the remote open ocean, as well as the multiscale nature of tropical cyclogenesis, which involves interaction of processes from the convective scale to the planetary scale.

According to the National Hurricane Center, “a tropical cyclone is a rotating, organized system of clouds and thunderstorms that originates over tropical or subtropical waters and has a closed low-level circulation.” Based on the maximum sustained wind speed (i.e., the Saffir–Simpson scale), tropical cyclones are categorized into tropical depressions, tropical storms, and category 1 to category 5 hurricanes. A tropical depression is a relatively weak tropical cyclone with maximum sustained winds of 38 mph (33 knots) or less, and a tropical storm has maximum sustained winds of 39–73 mph (34–63 knots). In tropical cyclone forecasting, genesis is typically considered to have occurred with the formation of a tropical depression or a tropical storm. In agreement with the definition of a tropical cyclone, one of the operational criteria for genesis is the presence of a closed low-level circulation. This criterion, however, introduces some ambiguity when a vortex is embedded in a strong environmental flow, since a vortex may appear open in the Earth-relative frame of reference. In tropical cyclone research, a loose but more physically based definition is often used, in which genesis is defined as the formation of a self-sustaining system.

Necessary Conditions for Tropical Cyclogenesis

Tropical cyclone formation is sensitive to some large-scale conditions. The necessary, but not sufficient, conditions for tropical cyclone formation were identified more than four decades ago and are summarized below:

1. warm ocean waters throughout a sufficient depth (sea surface temperature (SST) > 26 °C to a depth of 60 m);
2. enhanced midtroposphere (~700 hPa) humidity;
3. conditional instability;
4. a preexisting low-level cyclonic disturbance;

5. weak vertical shear of the horizontal winds at the genesis site; and
6. 5° minimum latitudinal displacement from the equator.

The warm ocean is the energy source for tropical cyclone formation and intensification. A deep layer of warm water ensures sufficient thermal energy from the ocean. As shown in [Figure 1](#), nearly all tropical cyclones form in oceanic regions with SST greater than 26 °C. Recent studies suggest that this empirical SST threshold increases with the tropical mean SST. As reported in the IPCC WGI Fifth Assessment Report, the global frequency of tropical cyclones is likely to either decrease or remain essentially unchanged in the twenty-first century while the global mean tropical cyclone maximum wind speed and rain rates are likely to increase.

The majority of tropical cyclones form between 20° S and 20° N ([Figure 1](#)), but genesis is rare within 5° latitude from the equator due to the weak planetary vorticity. One of the outliers is Typhoon Vamei in 2001, which was formed at 1.4° N in the South China Sea. The development was facilitated by the interaction between cold surges originating from higher latitudes and a low-level cyclonic circulation, which provided enhanced background vorticity.

Strong vertical wind shear is detrimental for tropical cyclogenesis as it displaces the midlevel warm core from the surface circulation. Strong vertical shear can also advect dry air into the storm and weaken moist convection. It is generally believed that tropical cyclogenesis is extremely unlikely when the vertical shear between 200 and 850 hPa exceeds 15 m s⁻¹.

Although numerical model simulations suggest that spontaneous tropical cyclogenesis is possible if favorable environmental conditions are available for a sufficiently long time period, a preexisting low-level cyclonic disturbance is one of the necessary conditions for tropical cyclone formation in the present climate. A cyclonic precursor disturbance not only enhances the absolute vorticity, but also promotes vorticity aggregation and protects the incipient tropical cyclone vortex from a hostile environment, as discussed in [Section The Marsupial Paradigm](#).

The SST exceeds the empirical threshold over vast areas in the tropics and varies slowly in time, but other environmental conditions (e.g., midlevel moisture, low-level vorticity, vertical shear, and convective instability) can be modified significantly on the synoptic to subseasonal timescales, which contributes to variations of tropical cyclone activity.

Figure 1 Long-term annual mean sea surface temperature (SST) and tropical cyclogenesis locations during 1971–2003. Note that although the long-term annual mean SST is less than 26 °C in some regions SST may exceed the threshold in the hurricane season.

Climatology of Tropical Cyclone Formation

The average annual number of global tropical cyclones with maximum sustained winds of 17 m s^{-1} or more is between 80 and 90, among which 40–50 intensify into hurricanes. Tropical cyclone frequency varies from basin to basin and from season to season. The climatology in different tropical basins is briefly described in this section. The statistics are derived from the International Best Track Archive for Climate Stewardship dataset (IBTrACS) for the time period 1974–2011. The numbers vary slightly depending on the time period examined or the dataset used.

Over the Atlantic, there are 12 tropical cyclones each year on average, which account for about 12% of the global storms. The Atlantic hurricane season runs from 1 June to 30 November, but tropical cyclones have been recorded in each calendar month except February and March. August and September are the peak season for tropical cyclone formation (**Figure 2(a)**), with about seven storms forming in these 2 months on average and 2–3 storms forming before August or after September. Tropical cyclogenesis location also has strong seasonal variations (see the genesis locations by 10-day period at <http://www.nhc.noaa.gov/climo>). Early in the hurricane season, tropical cyclones tend to form over the Gulf of Mexico and the Caribbean Sea. In the peak season, a large number of storms form over the Central and East Atlantic. These storms spend more time over the warm ocean and have a better chance to intensify into major hurricanes before making landfall or recurving poleward. In October and November, the genesis center shifts westward, and tropical cyclone formation is increasingly subject to extratropical impacts.

The East Pacific has 16 tropical cyclones per year on average. The hurricane season lasts from 15 May to 30 November, with a peak frequency in late August (**Figure 2(b)**). Most tropical cyclones form over a narrow band of warm SST and weak vertical wind shear north of the inter-tropical convergence zone (ITCZ) (**Figure 1**), a region of the highest genesis frequency per unit area over the globe. Tropical cyclones over the East Pacific may develop from tropical easterly waves originating over the Atlantic (or even West Africa) or from disturbances resulting

from the ITCZ breakdown. The latter sometimes leads to the simultaneous development of multiple cyclones.

The western North Pacific is the only basin where tropical cyclones form in all months of the year (**Figure 2(c)**). The genesis frequency peaks in August and September, with a minimum from January to April. On average, 26 tropical cyclones develop per year in this basin, which account for about 30% of the global storms. Tropical cyclogenesis in this basin is closely related to the monsoon circulation. Tropical cyclones frequently form in a monsoon trough or a monsoon confluence zone. Genesis may be associated with tropical easterly waves, equatorial Rossby waves, northwestward propagating tropical-depression disturbances, or the tropical upper tropospheric trough. Energy dispersion from a preexisting tropical cyclone may also spawn a new storm to its southeast. A giant typhoon occasionally develops near the center of a large-scale (radius of $\sim 1000 \text{ km}$) monsoon gyre.

There are only five tropical cyclones per year on average over the North Indian Ocean, with more storms forming over the Bay of Bengal than over the Arabian Sea (**Figure 1**). The seasonal cycle of the tropical cyclone formation has a bimodal distribution (**Figure 2(d)**), with a primary peak in November after the monsoon season and a secondary peak in May prior to the monsoon season. The reduced tropical cyclone (TC) activity during the monsoon season can be attributed to the strong vertical wind shear and the location of the monsoon trough. In the monsoon season, the monsoon trough shifts further northward and is located closer to land. Monsoon depressions, the primary precursor disturbances for tropical cyclone formation in this basin, form in the vicinity of the monsoon trough and tend to track northward over land, instead of moving westward over the warm ocean. Despite the low storm number, the deadliest storms have occurred in this basin. A tropical cyclone of moderate intensity may produce destructive storm surges in the Bay of Bengal due to the low and flat coastal plains and funnel-shaped coastlines. The 1970 Bhola cyclone killed more than 200 000 people in Bangladesh, and Cyclone Nargis in 2008 killed more than 100 000 in Myanmar.

In the Southern Hemisphere, tropical cyclones form over the South Indian Ocean and the western South Pacific. The

Figure 2 Seasonal cycle of 10-day mean tropical cyclone genesis frequency over different basins. The abscissa indicates the calendar months, and the ordinate is the number of storms per day multiplied by 100.

absence of tropical cyclones over the tropical South Pacific can be attributed to cold SSTs. Despite warm SSTs, tropical cyclones rarely develop over the South Atlantic because of the presence of the strong tropospheric (near surface to 200 mb) vertical wind shear and the absence of the ITCZ over the ocean. There are about 23 tropical cyclones per year on average over the southern Indian Ocean–Australia–the southwestern Pacific, and most of them form from November to April (**Figure 2(e)**). A large number of tropical cyclones develop near the northern coast of Australia (**Figure 1**), posing a great forecast challenge.

Variations of Tropical Cyclone Activity

Tropical cyclone frequency has strong variations on both the intraseasonal and longer timescales. On the intraseasonal timescale, tropical cyclone formation is strongly modulated by the Madden–Julian Oscillation (MJO). The MJO is the dominant mode of intraseasonal variability in the tropics. Its period varies between 30 and 60 days, and the local wavelength is roughly 12 000–20 000 km. The MJO is characterized by the eastward propagation of enhanced (and suppressed) convection in the tropics. The MJO affects tropical cyclone formation

through the modulation of the vertical wind shear, low-level vorticity, and midlevel moisture. As the active center of the MJO progresses eastward, the favored regions for tropical cyclone formation shift from the West Pacific to the East Pacific and eventually to the Atlantic (**Figure 3**). The hurricane genesis frequency in the Gulf of Mexico in the westerly (active) phase of the MJO can be four times as high as in the easterly (inactive) phase.

On the interannual timescale, tropical cyclone activity is strongly impacted by the El Niño–Southern Oscillation (ENSO). In the El Niño years (the positive phase of the ENSO), the ascending branch of the Walker circulation shifts eastward from the Maritime Continent–western Pacific sector to the Central Pacific due to SST warming over the Central and East Pacific. The change of the Walker circulation is accompanied by variations of the vertical wind shear and SST across the tropics. Cooler SST and stronger wind shear suppress tropical cyclone activity over the Atlantic and the western North Pacific, while warmer SST and weaker vertical shear contribute to enhanced tropical cyclone activity over the Central Indian Ocean, the East and Central Pacific. Conversely, tropical cyclone activity is enhanced over the Atlantic and the western North Pacific and reduced over the Central and East Pacific in the La Niña years.

Figure 3 Tropical cyclone genesis locations (circles) in different phases of the Madden–Julian Oscillation (MJO). The MJO phases are identified by the 200-hPa velocity potential anomalies. Positive values (brown shading) indicate where convection is suppressed, and negative values (green shading) indicate where convection is enhanced. Figure from the National Weather Service, Climate Prediction Center: http://www.cpc.ncep.noaa.gov/products/intraseasonal/intraseasonal_fa.html.

Besides the ENSO, tropical cyclone activity is also affected by other climate factors. For example, the Atlantic Meridional Mode modulates the Atlantic ITCZ and strongly impacts the tropical cyclone genesis frequency and location as well as the storm track and intensity. On the decadal to multidecadal timescales, Atlantic tropical cyclone activity is modulated by the Atlantic Multidecadal Oscillation.

Theories for Tropical Cyclogenesis

It is instructive to consider tropical cyclone formation as a two-stage process. The first stage is the preconditioning of

the synoptic- and subsynoptic-scale environment, and the second stage is the construction and intensification of the tropical cyclone proto-vortex. The two stages distinguish processes at different spatial scales but may overlap in time. Tropical cyclones can develop in different synoptic-scale environments. Five genesis pathways have been identified based on the upper-level forcing and the low-level baroclinicity: nonbaroclinic, low-level baroclinic, trough-induced, weak tropical transition, and strong tropical transition. The first two pathways are not involved with significant upper-level forcing and account for about 70 and 9% of the global tropical cyclone developments, respectively. Over the Atlantic and the East Pacific, these two genesis pathways are generally associated

with tropical easterly waves. A recently proposed theory for tropical cyclone formation within tropical easterly waves is summarized in Section [The Marsupial Paradigm](#).

Despite the variety of synoptic-scale environments or precursor disturbances, it is generally believed that tropical cyclone formation proceeds through essentially the same mesoscale evolution processes at the second stage. Theories for the construction and intensification of the tropical cyclone proto-vortex are highlighted in Section [Development of the Tropical Cyclone Proto-Vortex](#).

The Marsupial Paradigm

Over the Atlantic, about 60% of tropical cyclones and 85% of intense hurricanes originate from tropical easterly waves. These waves have a typical wavelength of 2500–4000 km, and propagate westward at the speeds of 5–10 m s⁻¹. The waves generally peak at the same altitude as the African easterly jet (600–700 hPa over Africa and the East Atlantic) and have a cold-core structure in the lower troposphere. How an intense, warm-core tropical cyclone develops from such a synoptic-scale wave is an intriguing question. Recent studies show that a region of approximately closed Lagrangian circulation within the wave critical layer (i.e., the Kelvin cat's eye) plays an important role in tropical cyclone formation. The wave critical layer is the region surrounding the wave's critical latitude in a latitudinally sheared flow. In the enclosed Kelvin cat's eye, particles are trapped and recirculate rather than being swept one way or the other by the surrounding shear flow ([Figure 4](#)). The cat's eye is hypothesized to be important for tropical cyclone formation in three ways. First, that wave breaking or roll-up of the cyclonic vorticity and moisture near the critical latitude in the lower troposphere provides a favorable environment for vorticity aggregation leading to tropical cyclone formation. Second, as a region of quasiclosed Lagrangian circulation, the cat's eye protects moist convection inside from dry air intrusion to some degree. Third, there is positive feedback from the moist convective vortices to the synoptic-scale wave. The wave is maintained and possibly enhanced by diabatically amplified mesoscale vortices within the cat's eye. The combination of the three hypotheses is labeled the marsupial paradigm as the cyclogenesis sequence is likened to the development of a marsupial infant in its mother's pouch. The cat's eye within the wave critical layer is dubbed the 'wave's pouch' or simply 'pouch.'

Cloud-resolving numerical model simulations and observational analyses further reveal the dynamic and thermodynamic properties of the wave pouch. In the inner wave pouch region (a meso- β -scale area around the pouch center), the flow is characterized by strong rotation and weak shear/strain deformation. Moisture lofted by convection from the boundary layer can accumulate in this region and effectively moisten the column, while it is spread out or distorted into filaments away from the pouch center because of the strong strain rate. The wave pouch center is thus the preferred location for deep convection. The organized convection near the pouch center drives the transverse circulation and spins up the system-scale circulation. Numerical model simulations and *in situ* observational data show that the midlevel equivalent potential temperature becomes several degrees higher in the

Figure 4 Formation of a tropical storm within a wave pouch. The dashed contours represent the streamlines in the ground-based frame of reference, which usually have an inverted-V pattern. The solid streamlines delineate the wave pouch as viewed in the frame of reference moving at the same speed with the wave. The pouch can protect the mesoscale vortices inside from the hostile environment, such as dry air associated with the Saharan air layer (SAL). Deep convection (gray shading) is sustained within the pouch. Owing to convergent flow, the pouch may have an opening that allows the influx of environmental air and vorticity. The easterly jet (JET), the critical latitude (CL), and the wave trough axis (Trough) are also indicated in the schematic. The intersection of the critical latitude and the trough axis pinpoints the pouch center as the preferred location for tropical cyclogenesis. inner pouch region than in the outer pouch region 1–2 days prior to genesis ([Figure 5](#)). The increase in the midlevel equivalent potential temperature in the inner pouch region is due to the accumulative effect of moist convection, and may serve as an indicator for organized convection and the impending tropical cyclogenesis.

The marsupial paradigm was originally proposed for tropical easterly waves. Subsequent studies show that it is also valid for tropical cyclone formation associated with other types of waves. Based on the marsupial paradigm, real-time forecast products have been developed to predict the genesis location using global model products. These products have provided useful guidance for flight planning in some recent tropical cyclone field experiments, including the Tropical Cyclone Structure field experiment in 2008 over the western North Pacific and the PREDICT field experiment in 2010 over the Atlantic.

Development of the Tropical Cyclone Proto-Vortex

There are two groups of theories regarding the development of the meso- β -scale tropical cyclone proto-vortex near the surface: the top-down development and the bottom-up development. The top-down theory suggests that the merger of multiple midlevel vortices in the stratiform precipitation

Figure 5 Left panel: Time–radius plots of saturation fraction (SF; %) derived from the numerical model simulation of Felix. Right two panels: vertical profiles of equivalent potential temperature (θ_e) for Karl and Matthew derived from the PREDICT dropsonde data. Solid lines and dashed lines represent the averages over the inner and outer pouch regions, respectively. Different colors represent different days prior to or after genesis. The plots show that θ_e increases up to 6 K prior to genesis in the inner pouch region but does not have any systematic increase in the outer pouch region. Adapted figure from Wang, Z., 2012. Thermodynamic aspects of tropical cyclone formation. *Journal of the Atmospheric Sciences* 69, 2433–2451. © American Meteorological Society. Used with permission.

region can create a vortex of a stronger intensity and a larger spatial scale. The vortex extends downward and engenders a cyclonic circulation near the surface, which is assumed to further intensify through the wind-induced surface heat exchange mechanism. It is also suggested that a midlevel vortex, with its associated cold core in the lower troposphere and warm core in the upper troposphere, modifies the thermodynamic environment and makes the vertical mass flux profile more bottom-heavy, which is favorable for the intensification of the low-level circulation.

The bottom-up theory emphasizes the role of vortical hot towers (VHTs), or rotating cumulonimbus clouds, in tropical cyclone formation (Figure 6). Although the lifetime of convective updrafts is of the order of 1 h, convective vorticity anomalies last much longer. Merger and axis-symmetrization of VHTs and their vortical remnants are hypothesized to lead to the formation of the proto-vortex. Furthermore, it is suggested that VHTs collectively act as a quasisteady heat source for driving the transverse circulation. The associated low-level convergence concentrates vorticity and intensifies the system-scale circulation.

Briefly speaking, the top-down development emphasizes the importance of stratiform processes and a midlevel vortex in initiating the surface cyclonic circulation, while the bottom-up development emphasizes the critical role of deep convection and the associated low-level convergence. While low-level convergence is the most effective way to intensify the surface circulation, it is worth noting that the bottom-up and top-down development routes may not be mutually exclusive. Different theories may be more relevant in different regions, and vorticity evolution at different spatial scales may take different vertical development routes. Besides, recent studies also suggest that other modes of moisture convection, besides VHTs, produce a wide range of vorticity anomalies and contribute to genesis. In

particular, cumulus congestus is proposed to play a dominant role in moistening the lower and middle troposphere and preconditioning the atmosphere for the transition to sustained deep convection and genesis.

Predictability of Tropical Cyclogenesis

A tropical cyclone is a meso- β -scale vortex, residing between the synoptic-scale waves and the meso- γ -scale convective processes. There is a downscale enstrophy cascade from the synoptic scale to the meso- β -scale and an upscale energy cascade from the convective scale (meso- γ -scale) to the meso- β -scale. Tropical cyclogenesis thus can be regarded as a combination of the large-scale downscaling and convective-scale upscaling processes. The large-scale environment to a large extent determines the track of the preferred genesis locations for storms originating from tropical waves, but moist convective processes limit the predictability of tropical cyclone formation, in particular, the genesis time. Predictability of tropical cyclogenesis can be evaluated using ensemble sensitivity experiments or adjoint modeling systems. Among various environmental parameters, tropical cyclone intensity forecasts are most sensitive to variations in midlevel moisture and low-level convective instability. Small errors in initial conditions can grow rapidly at the convective scale and then lead to strong divergence of the storm evolution in forecasts, similar to how moist convection limits the predictability of midlatitude winter storms. The predictability of tropical cyclone formation is also significantly influenced by vertical shear, and the forecast uncertainty increases with increasing vertical shear. The limited intrinsic predictability of tropical cyclone formation highlights the need to develop advanced ensemble prediction systems to provide probabilistic forecasts and risk assessment.

Tropical Cyclones and Climate Change

TR Knutson, NOAA Geophysical Fluid Dynamics Laboratory, Princeton, NJ, USA

© Published by Elsevier Ltd.

Synopsis

It remains uncertain whether any past changes in tropical cyclone activity measures exceed the levels expected from natural variability alone. Using statistical and dynamical simulations, the late twenty-first century projections of tropical cyclone activity have been constructed. Although the confidence in these projections is limited, the general picture that emerges is a warmer climate with roughly 20% fewer tropical storms globally, about a 5% increase in the average intensity of tropical cyclones, and possibly more of the most intense (Category 4 and 5) systems. An increase in the precipitation rates near tropical cyclones, by about 20%, is also projected. Rising sea levels are expected to exacerbate surge flooding risk, although the net change in surge risk will depend on changes in landfalling tropical cyclone climate.

Introduction

The term tropical cyclone refers collectively to hurricanes, typhoons, tropical storms, and weaker tropical depressions, all of which are cyclones that form over tropical ocean regions. Here we will use the term more strictly to refer to hurricanes, typhoons, and tropical storms. An important question regarding these storms is whether they may change in character in response to climate change. Here we use the term climate change to refer to long-term (multidecadal to century scale) changes in climate caused by human activities such as burning of fossil fuels. Thus we are concerned with whether tropical cyclones have already changed due to the global warming that has already occurred since the late 1800s, and how tropical cyclones would behave if the tropical climate warms substantially ($\sim 2^\circ\text{C}$) during the twenty-first century as projected by the Intergovernmental Panel on Climate Change (IPCC) Fourth Assessment Report (IPCC, 2007) for some typical anthropogenic emission scenarios. The science of tropical cyclones and climate change is interdisciplinary, involving both climate science and hurricane science. As such, scientists from these disciplines collaborate to address this research problem. Using tools such as long observational records of tropical cyclone activity and related climate records, they have sought clues to the past behavior of tropical cyclones and an understanding of how this behavior is linked to other aspects of climate change – both natural and anthropogenic. Scientists have also used theory and models to better understand the relationship between large-scale climate and tropical cyclone activity. Based on these combined activities – observations, theory, and modeling – scientific assessments have emerged, which will be reviewed here. It is emphasized that the science of tropical cyclones and climate change continues to evolve as new or improved observational evidence, theories, or models become available that can further enhance our understanding of the tropical cyclone–climate change connection.

In this article, we first review the issue from a historical perspective, describing some initial findings that pointed toward a possibly high sensitivity of tropical cyclone activity to the past climate warming. This led to concern about a possible dramatic future increase in tropical cyclone activity in response to projected twenty-first century climate warming. We then

review subsequent developments in the science which found that, after accounting for observing system changes, the estimated past changes in tropical cyclone activity were far less dramatic than the initial analyses had reported. These new findings then implied considerably lower estimates of the sensitivity of tropical cyclones to climate warming. As of this article, it remains uncertain whether any trends or changes seen in the past records of tropical cyclones are outside the range of natural variability.

Why Is There a Concern about Increased Tropical Cyclone Activity in a Warmer Climate?

Concern about a possible influence of global warming on tropical cyclone activity arose from several research findings that suggested a possible strong sensitivity of tropical cyclone activity to climate warming. First, scientists had long ago recognized that tropical cyclones are generally formed and intensified in relatively warm tropical and subtropical oceanic regions. In the context of global warming, this led to a speculation that tropical cyclones would become more prevalent or more intense as the tropical oceans became warmer. Second, scatter plots of the maximum intensities of tropical cyclones vs sea surface temperature (SST) (Figure 1) showed that upper limit intensity of hurricanes tended to increase over relatively warm waters and that in fact the most intense hurricanes do not occur over cool sea surfaces – further reinforcing the view of a strong climate warming/hurricane intensity link. Theoretical models of hurricane intensity suggested that the maximum intensity of tropical cyclones would increase in a warming climate, though not as strongly as the apparent relationship in scatter plots such as Figure 1. Third, multiyear fluctuations of tropical cyclone power dissipation, an aggregate measure of hurricane activity, were shown to be well correlated in the Atlantic basin with tropical Atlantic SST, especially on decadal timescales and extending back as far as 1950 (Figure 2). Fourth, initial studies of Atlantic tropical storm frequency trends extending back to the late 1800s and early 1900s revealed a doubling in the annual frequency of these storms over the twentieth century, with similar increases in hurricanes since 1900 as well (e.g., Figure 3, blue curve). Analyses of tropical

Figure 1 Scatter plot of observed tropical cyclone intensities vs SST in the environment of the storm. The most intense tropical cyclones occur only at relatively warm SSTs. Figure courtesy of Jim Kossin, University of Wisconsin/NOAA/National Climatic Data Center (NCDC).

Figure 2 Low-pass filtered tropical Atlantic SST (blue) vs the power dissipation index (PDI) (red) for North Atlantic hurricanes based on data through 2011. SST is averaged over 6–18° N, 20–60° W, August–October. The data for 1949–69 are bias-adjusted to correct for a high bias in the North Atlantic hurricane database (HURDAT) winds. No adjustments are made to account for incomplete sampling of tropical cyclone frequency, duration or intensity, which may adjust the earlier part of the record toward higher values of PDI. Atlantic SST (the second curve from the top in Figure 3) found a likely detectable anthropogenic component, which, assuming that the close correlation between the tropical Atlantic SST and hurricane activity shown in Figure 2 was causal, implied that a detectable human influence on hurricane activity could be indirectly inferred. Finally, an analysis of ‘Best Track’ data sets of tropical cyclone activity in multiple basins around the globe extending back to the mid-1970s revealed a pronounced widespread increase over time in the number and proportion of the most intense tropical cyclones.

Adding to this concern were the very active 2004 and 2005 Atlantic hurricane seasons, with 2005 being a particularly active year for Atlantic hurricanes, featuring an extremely costly US landfalling event – Hurricane Katrina in the New Orleans/Mississippi coast vicinity. Based on this confluence of research findings and notable storm events, the climate change/hurricane community seemed on the brink of declaring that a pronounced or even dramatic anthropogenic increase in Atlantic hurricane activity, and possibly global tropical cyclone activity as well, was already underway. The existing counterarguments to this view at the time focused on the lack of a trend in US landfalling hurricane activity and on the much smaller sensitivity of tropical cyclones to climate change being simulated by dynamical models, or being inferred from the theories of hurricane intensity. In particular, the model-projected changes were much smaller than the various hurricane change projections being inferred from trends in the historical observations.

At this point, however, a new series of studies began to challenge the view of a pronounced detectable anthropogenic influence on twentieth century hurricane and tropical cyclone activity. The new studies began to elaborate issues with several of the previous findings, with implications for the question of a detectable anthropogenic influence on hurricanes. These new studies and the conclusions drawn from them are discussed in the following section.

Has Anthropogenic Climate Change Altered Tropical Cyclone Activity?

Detection of a climate change, as used here, refers to demonstrating that an observed change is highly unusual compared to the changes expected from natural processes alone, so that the change is likely to have been caused at least in part by anthropogenic forcing agents, such as increased greenhouse gases. An example of such a detectable climate change is the global mean temperature record since the late 1800s shown at the top curve in Figure 3. The increase in global mean temperature is broadly considered detectable because, among other findings, the increase is similar to that simulated in climate models that incorporate changes in greenhouse gas forcing and aerosols, while it cannot be simulated in models that do not include the warming influence of increased greenhouse gases.

Since credible century-long simulations of hurricane activity, including multicentury pre-industrial simulations, were

generally not available from current climate models, owing to their limited horizontal resolution, a simplified form of climate change detection with regard to Atlantic hurricanes was initially undertaken. The approach was to test whether a significant long-term trend, similar to that seen for global mean temperature or tropical Atlantic SST (top two curves) in [Figure 3](#), was also present for Atlantic hurricane frequency. While such an increase was indeed found for the hurricane counts (blue curve in [Figure 3](#)), independent research teams began to question the completeness of the observed Atlantic hurricane count record, particularly for hurricanes that remained at sea and never made landfall. Prior to the aircraft reconnaissance in the 1940s and especially prior to the satellite observing era in the mid-1960s, vast regions of the Atlantic were not systematically monitored for hurricane or tropical storm occurrence, and thus historical frequency estimates relied on essentially chance encounters between the storms and ships at sea. Although meteorologists have made a strong effort to identify missing storm cases based on available records, the question remained whether there was a dense enough network of ships available during the early part of the record to detect the non-landfalling storms that existed during that period. At least two independent groups concluded that there very likely was not a dense enough network of shipping traffic to adequately detect all the storms of the late 1800s and early 1900s. The red curve in [Figure 3](#) (fourth from the top) labeled ‘adjusted hurricane counts’ shows an estimate of what the actual history of Atlantic basin-wide hurricane counts would have been if the basin had adequate ship track density over the entire period so that no storms would have been missed. The adjusted curve has a negligible long-term trend. Interestingly, its time evolution bears a strong resemblance to that of the US landfalling hurricanes (orange curve in [Figure 3](#)), which suggests that the adjustments made to the basin-wide record are at least plausible. The two curves would be expected to be similar if the fraction of hurricanes that made landfall were unchanging over time; however, the assumption of constant landfalling fraction is not particularly compelling, necessitating the ship track density analyses. In summary, the long-term records of Atlantic hurricanes and tropical storm counts, after being assessed for potential problems with missing storms early in the record, do not provide compelling evidence of an anthropogenic influence in the form of a long-term rising trend.

The close correlation between multiyear fluctuations of Atlantic hurricane power dissipation and tropical Atlantic SSTs ([Figure 2](#)) is apparently not as influenced by ship track density issues as the century-long hurricane basin-wide frequency record, since the analysis in [Figure 2](#) begins around 1950, when aircraft reconnaissance was already available for monitoring hurricanes that were threatening landfall. A critical aspect of the relation shown in [Figure 2](#) is that it is a statistical correlation, which does not necessarily imply causation. In this case, independent investigators examining these data sets found that an alternative SST index to the local tropical Atlantic SST used in [Figure 2](#), was also strongly correlated to the power dissipation series. [Figure 4](#) shows a comparison of the statistical fit between historical hurricane activity and historical SST using two different statistical indices. The upper panel in [Figure 4](#) shows the relationship between hurricane activity and local tropical Atlantic SST, while the bottom panel shows the same, but using a ‘relative sea surface temperature’ index, defined as

the tropical Atlantic SST minus the tropical average SST. (An even longer record of relative SST fluctuations, which has no long-term rising trend, is shown at the bottom of [Figure 3](#).)

The findings illustrated in [Figure 4](#) had two important implications. First, they showed that projections of the late twenty-first century Atlantic hurricane power dissipation based on statistical models could vary from a slight increase to a dramatic 300% increase depending on whether the relative SST or the local tropical Atlantic SST was used as a predictor. Second, the analysis implied that a detectable human influence on past Atlantic hurricane could be indirectly inferred from the SST data, but only if one used the local SST as the statistical model of hurricane activity, and not if one used the relative SST as the statistical model. Clearly, the choice of statistical model had a dramatic impact on both future projections of hurricane activity and on the interpretation of past hurricane activity. The analysis in [Figure 4](#) also showed that if one used the dynamical model projections of the late twenty-first century hurricane activity (rather than statistical models) the results (depicted by the symbols at the right side of the diagrams in [Figure 4](#)) strongly favored a lower sensitivity scenario (lower panel) with only relatively small changes in power dissipation projected on average for the late twenty-first century – smaller in magnitude than the twentieth century multidecadal variations.

Another study had found – through an analysis of ‘Best Track’ data sets of tropical cyclone activity in multiple basins extending back to the mid-1970s – a pronounced increase over time in the number and proportion of the most intense tropical cyclones at the global scale, and over multiple independent basins. In response to this study, and to concerns expressed by other hurricane scientists of likely problems with the tropical cyclone historical data sets, a highly specialized satellite-based data set of tropical cyclone intensities was developed that encompassed all tropical cyclone basins and attempted to remove any artificial trends or jumps in the data series. The strategy used was to keep the tropical cyclone intensity estimation procedure as constant over time as possible through the use of carefully screened multi-basin satellite data. This involved, for example, degrading the quality of the satellite data in later years of the record so that they would be more compatible with data from the earlier years. This approach supported earlier findings of increasing storm intensities of strong storms in the Atlantic basin since the early 1980s, but revised downward the trends estimated from the ‘Best Track’ tropical cyclone data in several other basins. Using this method, a large increase in intensities of the strongest Atlantic hurricanes since 1983 was assessed to be statistically significant. This change has not been generally regarded as indicating a detectable anthropogenic change because the record length was relatively short, given the existence of pronounced multidecadal variability over the twentieth century in the basin. The notion that a trend since 1983 should not be taken as necessarily representative of the longer term trend behavior in the basin can be seen by inspection of the various century-scale Atlantic hurricane-related time series in [Figure 3](#).

In short, while initial studies had pointed to the likely emergence of an anthropogenic climate change signal in the Atlantic hurricane and global tropical cyclone data, subsequent studies identified substantial problems with the underlying data sets and proposed alternative statistical interpretations of

Figure 4 Past and extrapolated future changes in Atlantic hurricane PDI from statistical models. Anomalies are regressed onto (a) tropical Atlantic SST or (b) tropical Atlantic SST relative to tropical mean SST (1946–2007), and these regression models are then used to statistically estimate the PDI from several climate models. Anomalies are percent change relative to 1981–2000 average ($2.13 \times 10^{11} \text{ m}^3 \text{ s}^{-2}$). The green bar denotes approximate range of the PDI anomaly predicted by statistical–dynamical calculations. The green circle, star, and diamond denote approximate values suggested by several high-resolution dynamical models. SST region is $20\text{--}70^\circ \text{ W}$, $7.5\text{--}22.5^\circ \text{ N}$. Source: Vecchi, G.A., Swanson, K.L., Soden, B.J., 2008. Whither hurricane activity. *Science* 322 (5902). <http://dx.doi.org/10.1126/science.1164396>.

the data. These developments led several recent tropical cyclone–climate change assessments (see [Further Reading](#)), to conclude that it remained uncertain whether any changes in observed tropical cyclone metrics were outside the range of natural variability.

What Are the Near-Term Prospects for Identification of a Human Influence on Tropical Cyclones?

Although no detectable human influence on tropical cyclone activity has been identified, according to recent assessments, one can ask what the prospects are for such a detection in the near future. Here we discuss several tropical cyclone changes that have been reported that may be good candidates in the near term for identifying a detectable human influence on hurricanes.

As one possible candidate, a century-scale record of land-falling intense tropical cyclones in northeastern Australia has been found to have a statistically significant decreasing trend over time. This is a reasonable candidate for a climate change detection given both the length of record involved and the finding that the trend is significant by conventional statistical tests. One concern about a climate change detection claim in this case is the distinction between the observed changes (decreasing frequency trend) and trends that could occur due to natural processes alone. The Pacific basin is characterized by pronounced internal (natural) variability on interannual (2–7 years) timescales associated with El Niño/Southern Oscillation (ENSO) and there is also evidence of decadal to multidecadal scale internal variability, often referred to as the Interdecadal Pacific Oscillation. In order to make a more robust climate change detection, a long (multicentury) simulation of natural variability of tropical cyclone activity in the

region would be desirable, so that an analysis similar to that used for global mean temperature could be undertaken. Features of the model-simulated variability could be compared to observations on various timescales to provide further information on the capability of the model to simulate variability representative of that in the real world. New simulations of tropical cyclone activity with higher resolution coupled climate models are becoming available, and improving in quality, which may facilitate such an analysis.

A second candidate for possible near-term tropical cyclone climate change detection is the temporary lull in hurricane activity that occurred in the North Atlantic basin in the late twentieth century. This epoch, clearly apparent in [Figures 2 and 3](#), was marked by relatively low levels of hurricane activity (particularly for major hurricanes) during the 1970s and 1980s, compared with the higher levels of the 1950s and 1960s, and from 1995 through at least 2012. Two leading hypotheses to explain this prominent multidecadal variation focus on explaining the causes of the similar multidecadal variations in SST that apparently caused the changes in hurricane activity. The two hypothesized causes of the SST variations include natural multidecadal variability (often termed the Atlantic Multidecadal Oscillation (AMO)) and changes in anthropogenic climate forcing (primarily from aerosols). The aerosol forcing hypothesis concerns the strong increases in aerosol forcing from North American sources from the 1940s through the 1970s with a substantial reduction in this aerosol forcing through the 1980s as stronger policies to reduce air pollution came into force in North America. There is no consensus at this time regarding the relative contribution of these two processes to the observed SST or hurricane changes. For example, some models simulate a strong response in the Atlantic to the changes in aerosol forcing, while other studies suggest that the vertical structure of the ocean temperature changes during the multidecadal event seem inconsistent with a surface forcing such as aerosols and more consistent with an internal climate variation such as the AMO, as simulated in climate models.

Also in the Atlantic basin, one study has attempted to reconstruct the twentieth century US landfalling tropical cyclone activity using a network of tide gauges. Although the authors find a statistically significant increase in the frequency of large surge events, questions remain about precisely how their index relates to hurricane activity and whether the changes they find in the surge index are highly unusual compared with natural climate variability.

A complementary approach is to address the question of *when* a detectable human impact on hurricane activity might be identified. This approach uses model projections of future tropical cyclone changes, under certain assumed emission scenarios, to estimate a detection timescale, or likely time of detection. One study has estimated that even assuming a 10% increase per decade in Category 4 and 5 hurricane frequency in the Atlantic basin, a time period of about six decades would still be required for the signal to be detectable above the background of natural variability. This long timescale for detection is related to the apparently large levels of natural variability of tropical cyclones and related metrics in the Atlantic basin; if most of the observed multidecadal variability turned out to be forced by anthropogenic activities, rather than due to natural variability, the expected detection timescale would be shorter.

Model Simulations of Present-Day Tropical Cyclone Activity

To explore how tropical cyclone activity may respond to future climate change will require the use of models to simulate the tropical cyclone activity. It is therefore necessary to first assess how well models can simulate the present-day climate of tropical cyclones. An example of a simulation of tropical cyclone genesis and tracks using an atmospheric model with prescribed SSTs is shown in [Figure 5](#), which compares observed tracks for the period 1981–2005 with the model-simulated tracks for those same years. The model generates its own storms based on the interactions within the model. These do not correspond to individual storms in the real world but have a similar distribution in a statistical sense. As another measure of model skill, [Figure 6](#) shows how the annual number of Atlantic hurricanes generated by the model in [Figure 5](#) varies from year to year compared with the observed record of hurricanes. The model is able to simulate the year-to-year variability of hurricane counts remarkably well using the observed SSTs as input. Several other atmospheric models show a roughly similar skill for this type of simulation test. The main point is that current models can translate large-scale information, such as the global SST distribution, into fairly realistic information about aggregate Atlantic hurricane activity. The simulations of year-to-year tropical cyclone variability in other basins are typically not as impressive as for the Atlantic basin, but models show some skill in several other basins. These results suggest that the current models in principle can be used to simulate changes in tropical cyclone activity in response to climate change such as global warming; however, the models rely on the SST patterns used as boundary conditions to be realistic, and these must be obtained elsewhere.

An Introduction to Tropical Cyclone Activity Projections for the Late Twenty-First Century

In the previous sections, we considered the issue of detecting an anthropogenic climate change influence on tropical cyclone activity, using past observations together with various statistical or dynamical models. Here we consider future (late twenty-first century) anthropogenic climate change, in which the global warming is expected to be considerably larger in magnitude than the changes experienced over the twentieth century, and ask what impact such changes could have on tropical cyclone activity.

The general approach is to use the projected climate changes for the late twenty-first century, as projected by various climate models (such as those used for the Coupled Model Intercomparison Project 5 (CMIP5)) and either track the changes in tropical cyclones simulated directly in those climate models, or use higher resolution atmospheric models or statistical models to ‘downscale’ the tropical cyclone activity based on large-scale fields obtained from the global climate models. (‘Downscaling’ here refers to the use of a statistical model or dynamical model to try to simulate the behavior of certain smaller scale weather or climate phenomena, such as hurricanes, that are poorly resolved in the global climate models due to the large spacing between grid points in those models. For example, the SSTs from a global climate model may be used as boundary forcing

Figure 5 Comparison of tracks for tropical cyclones that reached hurricane force for 1981–2005 from observations (top) and from a 50-km grid global atmospheric model running over observed SSTs for the same time period (bottom). From Zhao, M., Held, I., Lin, S.-J., Vecchi, G.A., 2009. Simulations of global hurricane climatology, interannual variability, and response to global warming using a 50 km resolution GCM. *Journal of Climate* 22, 6653–6678.

Figure 6 Annual number of observed (red) and simulated (blue) hurricanes in the Atlantic basin (1981–2008). The simulation uses an atmospheric model running over observed SSTs. The gray shading is the range of results across a five-member ensemble, with the blue line being the ensemble mean of these members. Dashed lines are least square linear trend lines. Updated from Zhao, M., Held, I., Lin, S.-J., Vecchi, G.A., 2009. Simulations of global hurricane climatology, interannual variability, and response to global warming using a 50 km resolution GCM. *Journal of Climate* 22, 6653–6678.

for an atmosphere-only model that has higher spatial resolution for resolving hurricane-like features more realistically.)

Before discussing the model projections, a brief discussion of confidence levels for these projections is needed. As discussed in the previous sections, there is as yet no clear detectable anthropogenic influence on tropical cyclone activity. This does not necessarily mean that no such detectable change is expected in the coming century, or that anthropogenic forcing has not yet affected tropical cyclones at all. First, the global mean temperature change over the twenty-first century in the IPCC Fourth Assessment Report (AR4) future emission scenarios is projected to be much larger than the temperature change over the twentieth century ($\sim 0.6^\circ\text{C}$), with a range of 'best estimate' global warming of about $1.8\text{--}4.0^\circ\text{C}$ depending on the IPCC Special Report on Emission Scenarios (SRESs) used (ranging from an aggressive emission reduction scenario B1 to fossil fuel-intensive scenario A1FI). Second, the observing system for tropical cyclones over the next century will undoubtedly be better than that over the twentieth century as a whole, making climate change detection studies more reliable. Third, the longer records available with additional decades of data make climate change detection more viable. However, given that no clearly detectable anthropogenic change in tropical cyclones has been identified yet, the confidence levels for projections of changes in tropical cyclone activity over the twenty-first century must necessarily be substantially lower than those for certain other climate variables (e.g., global mean surface temperature) that have strong evidence for a detectable anthropogenic signal over at least the past half century. The term 'likely' here is used to mean that the probability that the projected twenty-first century change will occur (assuming a twenty-first century emission scenario similar to IPCC SRES A1B – roughly a 'middle of the road' scenario) is subjectively assessed as about two chances in three or greater (but not 90% confidence, for example, which would be characterized as 'very likely').

Tropical Cyclone Frequency Projections

More than two dozen different studies have been done with various types of dynamical models of the atmosphere or atmosphere–ocean system aimed at simulating tropical cyclone frequency under warmer climate conditions. A common feature across 10 of these studies that explored global tropical cyclone activity is a decrease, ranging from a few percent to about one-third, in the total global annual count of these storms. The decrease is not seen in all individual basins in these models and is more pronounced in the Southern Hemisphere tropical cyclone basins than in the Northern Hemisphere.

The reasons for the decrease in global tropical cyclone frequency in the models are not well understood, partly because a full generalized theory of tropical cyclone genesis has not been developed. For example, although we know that about 90 tropical cyclones form each year in the current climate, we do not yet have a theory for why this number is 90 and not half or twice this number. Since atmospheric models can be made to produce a wide range in annual number of tropical cyclones through adjusting certain model parameters, they cannot offer an explanation directly. (Any such model

adjustment parameters are held fixed for climate change perturbation experiments such as those described above.) These fundamental questions remain a challenge for the tropical cyclone and climate research communities, although clearly progress has been made in our ability to model aspects of tropical cyclone climate, and even toward providing improved seasonal dynamical predictions of tropical cyclone activity, especially in the Atlantic basin.

Based on consistent projections from models, but tempered by the lack of a detectable decrease in the past data and by absence of a clear understanding of the physical mechanism producing the simulated decrease in the models, the projection of a global decrease in tropical cyclone frequency has been assessed as 'likely.'

An example of four maps of tropical cyclone frequency change projections for the late twenty-first century is shown in [Figure 7](#). The projections are from a single atmospheric model, but use projected SST changes from several different climate models. The fact that the detailed regional tropical cyclone frequency changes differ so much across the different projections suggests the following implication: even if climate scientists had a perfect model for translating future SST projections into tropical cyclone frequency projections, they would still have difficulty making confident tropical cyclone projections at the regional scale because different climate models disagree on important details of SST projections. That is, even though climate models all agree that global mean temperature will increase over the twenty-first century under the IPCC SRES scenarios, the detailed patterns in those warming projections differ between the models, and those differences apparently have important consequences for regional tropical cyclone activity.

These results suggest a long-term path forward toward more confident future projections of regional tropical cyclone activity: that the climate change research community eventually reduces the uncertainty of regional surface temperature projections, at least for a given emission scenario. Meanwhile, researchers can at least identify the more robust subset of projection signals for certain geographical domains (e.g., global, Southern Hemisphere) based on the existing models.

Tropical Cyclone Intensity Projections

In contrast to the decrease in global tropical cyclone frequency projected under climate warming by current models, the average intensity of tropical cyclones and the intensities of the strongest storms are projected to increase over the twenty-first century by roughly 5% in terms of maximum surface wind speed.

The maximum intensity of tropical cyclones has a more well-established theoretical basis and the ability to simulate tropical cyclone intensities with models has improved over time. Although the short-term (1–5 days) prediction of tropical cyclone intensity for individual storms remains a challenge and is much more difficult than storm track prediction, current theories and models at least produce credible climatological statistics of tropical cyclone intensities for the present-day climate, encouraging their use for climate change projections.

An early study in 1987 suggested that the maximum intensity of tropical cyclones could be successfully reproduced

Figure 7 Model-projected changes in tropical cyclone occurrence frequency for the late twenty-first century obtained using three different climate model projections of SST changes, or using an 18-model average change. Red colors indicate increases and blue colors decreases. Adapted from Zhao, M., Held, I., Lin, S.-J., Vecchi, G.A., 2009. Simulations of global hurricane climatology, interannual variability, and response to global warming using a 50 km resolution GCM. *Journal of Climate* 22, 6653–6678.

from a theory linking the intensity to the SST and vertical thermodynamic structure of the large-scale environment around the storm. The theory, developed by Kerry Emanuel at MIT, proposed that the environmental changes for CO₂ warming simulated by climate models implied that tropical cyclones would become more intense in a warmer climate. Dynamical modelers later found a similar sensitivity of tropical cyclone intensity to greenhouse warming using hurricane simulation models. Since then, a growing number of studies employing increasingly realistic higher resolution models (grid spacing from about 50 km down to about 10 km or less) have found a roughly similar sensitivity, at least globally. The range of values for global mean changes in these studies varies from a few percent to about 10%. The increased intensity is often not found using relatively coarse resolution models, which may not be too surprising, since these models only very crudely resolve a hurricane-like structure and often do not simulate such distinct features of strong tropical cyclones as the ‘eye’ at the center of hurricanes and typhoons. While a global mean increase of tropical cyclone intensity with climate warming is assessed as ‘likely,’ such increases are not projected to occur in all regions due to various regional patterns in projected surface warming and other factors.

Projected Frequency of Very Intense Tropical Cyclones

An increase of average tropical cyclone intensity would generally be expected to lead to an increase in the number of very intense storms. However, since model projections also indicate a likely decrease in the overall number of tropical cyclones,

there remains the question of whether the number of intense storms will increase or not. Furthermore, very intense (Category 4 and 5) tropical cyclones are typically not produced by atmospheric models unless the resolution is quite high (grid spacing of about 10–20 km or less, depending on the model). At least two studies using such models are currently available – one for the Atlantic basin using a regional hurricane model coupled to an ocean model, and the other using a global atmospheric model but with no interactive ocean model component. These studies both indicate that despite the reduced overall frequency of tropical cyclones in either the Atlantic basin or global domain they studied, the frequency of the most intense tropical cyclones tended to increase (e.g., Figure 8). However, there are only relatively few studies to date with sufficient resolution to simulate the frequency of very intense storms, and the statistical robustness of the projected changes even in these available experiments is marginal. Considering such factors, a recent assessment concluded that there were greater than even odds (>50% chance) of an increase in the frequency of very intense tropical cyclones over the twenty-first century.

While the confidence in such a projection is limited, the importance of such a future change could be considerable owing to the fact that very intense storms have caused a disproportionate fraction of tropical cyclone damage, according to historical analyses. It is also worth noting that such historical damage-based analyses, when adjusted for changes in demographics such as wealth and population, do not show strong evidence for a climate-change-related increase in tropical cyclone activity over time. Instead they indicate a prominent role for demographic changes in explaining historical increases in tropical cyclone damage observed over the twentieth century.

Figure 8 Tracks and intensities of all storms reaching Category 4 or 5 intensity (maximum surface winds $\geq 59 \text{ m s}^{-1}$) in a series of Geophysical Fluid Dynamics Laboratory (GFDL) hurricane model downscaling experiments (27 seasons). Results are shown for the control climate (upper left) and for downscaling experiments using the CMIP3/A1B 18-model ensemble climate change for the late twenty-first century (bottom left); CMIP5/Representative Concentration Pathways (RCP4.5) models early twenty-first century ensemble (upper right); and CMIP5/RCP4.5 late twenty-first century ensemble (lower right). The track colors (legend) depict the Saffir–Simpson category of the storms along their trajectories. CMIP3/A1B and CMIP5/RCP4.5 are two commonly used, representative future emission scenarios. From Knutson, T.R., Sirutis, J.J., Vecchi, G.A., Garner, S.T., Zhao, M., Kim, H.-S., Bender, M.A., Tuleya, R.E., Held, I.M., Villarini, G., 2013. Dynamical downscaling projections of twenty-first-century Atlantic hurricane activity: CMIP3 and CMIP5 model-based scenarios. *Journal of Climate* 22, 6591–6617. doi:10.1175/JCLI-D-12-00539.1.

Tropical Cyclone Rainfall Rate Projections

Perhaps the most robust projection from models concerning future tropical cyclone activity, in terms of both model consistency and physical understanding, is that the average precipitation rate in the vicinity of tropical cyclones is expected to increase. This could be important for future damage because inland flooding from tropical cyclone rainfall has

caused considerable damage and loss of life in the historical period. The projected fractional increase in rain rate obtained from models seems to depend on the averaging radius considered. In a recent study, the rate increased by about 10% for an averaging radius ranging from 200 to 400 km. The rainfall rate increased by as much as 30% or more (Figure 9) when averaged over a smaller region (50 km radius about the storm center).

Figure 9 Hurricane-related precipitation rate changes in percent for two different hurricane simulation models (Zetac and GFDL/GFDL-Navy version (GFDN)) and for two different sets of climate model input (CMIP3 and CMIP5). The dashed lines show the approximate increase in water vapor content in the environment of the storms. The rain rate increases by about the same percentage as the water vapor content, except near the storm ($< 100 \text{ km}$ from center) where the percent increase in rainfall rate is even larger than that for the environmental water vapor. From Knutson, T.R., Sirutis, J.J., Vecchi, G.A., Garner, S.T., Zhao, M., Kim, H.-S., Bender, M.A., Tuleya, R.E., Held, I.M., Villarini, G., 2013. Dynamical downscaling projections of twenty-first-century Atlantic hurricane activity: CMIP3 and CMIP5 model-based scenarios. *Journal of Climate* 26, 6591–6617. doi:10.1175/JCLI-D-12-00539.1.

The physical mechanism for the rainfall increase involves an increase in moisture-holding capacity of the atmosphere at higher temperatures. As the climate warms in models due to increasing greenhouse gas concentrations, a robust response is that the relative humidity in the lower troposphere does not change very much. Since warmer air at a given relative humidity holds more water vapor than cooler air, the tropical atmosphere in the warmer climate is projected to contain significantly more water vapor (about 7% more for every 1 °C rise in tropical SST, shown schematically by dashed lines in Figure 9). For a tropical cyclone, most of the moisture being rained out of the storm (at least within 400 km or less from the center) is fed by water vapor converged into the storm by the winds, rather than being evaporated from the ocean within the 400 km radius region. Thus, with climate warming the atmosphere holds more water vapor, so this moisture convergence is enhanced, and the precipitation rate consequently increases. Increased intensity of the cyclone circulation can further enhance the moisture convergence.

Influence of Sea Level Rise on Tropical Cyclone Storm Surge

Storm surge, which is a surge of ocean water onto the land associated with a tropical cyclone, is responsible for most of the deaths globally in tropical cyclones, and for a considerable fraction of the physical damage. The surge is caused mainly by the winds associated with a storm, although the low surface pressure also contributes. The magnitude of the surge depends on a number of factors, such as the near-shore bathymetry, the angle of 'attack' of the storm at the coastline, the storm size and intensity, and the timing and magnitude of the tide.

A robust projection of global climate models is a rise of global mean sea level over the next century. According to the IPCC AR4 report, the average rate of global mean sea level rise over the twenty-first century will very likely exceed that observed during 1961–2003 for a range of future emission scenarios. Projections of sea level rise over the twenty-first century remain uncertain due to a limited understanding of the likely contributions to sea level rise from the Greenland and Antarctic ice sheets.

Although the magnitude and regional distribution of the sea level rise have considerable uncertainty, an increase in sea level would be expected to exacerbate storm surge risk, all other factors being equal. In fact, much of the impact of sea level rise may be experienced through the interaction of sea level rise with extreme events such as tropical cyclones or other large coastal storms. In order to project whether storm surge damage will increase at a location and if so by how much, one needs to know not just the regional sea level change, but also the future changes in storm climate, such as landfalling frequency, tracks, size, intensity, and so forth at a location. This makes the projection of future storm surge damage a challenging research topic that is now beginning to be explored.

Summary and Conclusions

It remains uncertain whether any past changes in various tropical cyclone metrics (frequency, intensity, rainfall rates, and so

forth) exceed the levels expected from natural variability alone. Early analyses that appeared to show strong rising trends in several tropical cyclone indices and strong statistical relationships between storm activity and rising SSTs in the tropical Atlantic basin, were followed by other studies showing that observing system changes over time were likely responsible for the most pronounced trends. The lack of a clearly detectable climate change signal in past data limits our confidence in future projections of tropical cyclone activity for the twenty-first century, especially in comparison to other climate variables such as global mean surface temperature, where a much more robust climate change detection and attribution to human activities has been established and future projections are more confident.

Owing to the potential importance of the issue of tropical cyclones and climate change, attempts to infer future changes in tropical cyclones, using projected large-scale environmental changes from climate models, have received considerable attention. Relevant environmental changes include features such as oceanic warming, tropospheric warming, increased water vapor, sea level rise, atmospheric circulation changes, and even changes in the CO₂ concentration alone. Using various statistical modeling and dynamical simulation methods, the future (late twenty-first century) picture that emerges is a warmer climate with roughly 20% fewer tropical storms globally, about a 5% increase in the average intensity of tropical cyclones, and possibly more of the most intense (Category 4 and 5) systems. Owing to the higher atmospheric water vapor content, an increase in the precipitation rates near tropical cyclones, by about 20%, is also projected. These changes are projected to occur against a backdrop of rising sea levels, which, at least without considering changes in tropical cyclone climate, would lead to a greater risk of storm surge flooding.

Tropical Cyclones in the Western North Pacific

JCL Chan, City University of Hong Kong, Hong Kong

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

This article presents a climatology of tropical cyclones in the western North Pacific ocean basin, as well as the mechanisms of genesis of these cyclones in this ocean basin. Some unique features of the cyclone tracks and the variations of tropical cyclone activity in this ocean basin on different temporal scales are also described.

Introduction

Marks (2003) presented an overview of the climatology, structure, formation, and motion of a tropical cyclone (TC) as well as the interaction of the TC with the ocean, the hazards associated with a TC, and the state of art in the forecasting of TCs. In this article, we will focus on the TCs in one particular ocean basin – the western North Pacific (WNP). As will be seen below, WNP is the ocean with the highest annual number of TCs almost every year as well as the highest number of intense TCs. It is thus of interest to study in greater detail TCs in this ocean basin.

In this article, we will first present the climatology of TCs in this ocean basin, followed by the mechanisms of genesis. Some unique features of the TC tracks in the WNP will then be described. The large variations of TC activity in this ocean basin on various temporal scales will also be discussed in relation to various atmospheric phenomena. The structure of TCs in the WNP will not be included because it is the same as those in other basins and has been presented in detail in Marks (2003). The mechanisms of intensification are also not unique in the WNP and will also not be discussed. Interested readers should refer to Marks (2003).

Climatology

As can be seen from Figure 1, TCs can form throughout the 12 months of the year, with the maximum occurrence of six or

Figure 1 Average number of TCs in the western North Pacific in each month during the period 1959–2011. Data source: US Joint Typhoon Warning Center.

more in August on the average. During the period 1959–2011, the mean annual total number of TCs is close to 31, which is the highest among all tropical ocean basins. Of these, about 17 reach typhoon intensity (maximum sustained winds (MSWs) near the earth's surface $\geq 118 \text{ km h}^{-1}$), close to 10 could only attain either severe tropical storm (MSW: $88\text{--}117 \text{ km h}^{-1}$) or tropical storm intensity (MSW: $63\text{--}87 \text{ km h}^{-1}$), and the rest are tropical depressions (MSW $< 63 \text{ km h}^{-1}$).

A large year-to-year variation of TC activity in the WNP exists, as can be seen from the annual number of TCs during the period 1959–2011 (Figure 2). The annual number of TCs varies from a high of 44 in 1964 and 1996 to a low of 19 in 2010, and apparently goes through a multidecadal cycle, with maximum in the 1960s and 1990s, and a minimum in the late 1970s, and in the recent decade. There also appears to be a downward trend, with a decrease of around one TC per decade. A similar multidecadal cycle can also be found in the annual number of typhoons (blue curve in Figure 2). A correlation of ~ 0.7 exists between the two time series. A more detailed discussion of these variations will be presented later in this article on the climatic variations.

Genesis

The WNP has the largest area of high sea-surface temperature (SST) among all tropical oceans (see Figure 3 in Marks, 2003), with the area of over 27°C covering almost the entire ocean basin. As a result, the thermodynamic conditions necessary for genesis (see Marks, 2003) are satisfied throughout the year. Therefore, if the dynamic conditions can also be satisfied, TC genesis can occur.

In the WNP, a monsoon trough is present from about May to October each year, which can be seen from the flow pattern in the lower troposphere (Figure 3). In the tropical region, the west to southwesterly flow extends from the Indochina region into the South China Sea. At the same time, two cross-equatorial flows, one between 110 and 130°E and another between 140 and 160°E converge east of the Philippines. These three flows then form the monsoon trough that extends from northern Vietnam through Hainan Island and south-eastward through the Philippines, and ends at around 140°E . The relative vorticity distribution over the ocean basin also shows a similar feature (Figure 4). The highest vorticity patch stretches from the South China Sea all the way to the dateline. Thus, convective clusters that form within this strip of high

relative vorticity already have the background vorticity condition satisfied. What it takes is a trigger to spin up the cluster.

In a majority of cases, the trigger comes from the Southern Hemisphere in the form of a monsoon surge (Figure 5). As a cold front in the Southern Hemisphere advances northward, the subtropical high is pushed toward the equator. This causes a pressure rise across the equator, triggering a southwesterly flow. If this is coupled with an enhancement of easterlies in the

Northern Hemisphere due to an intensification of the subtropical high, additional positive vorticity will be injected into a preexisting cluster, providing it with enough spin to become a TC.

Another trigger occurs in May and June over the South China Sea associated with a Mei-yu front (Figure 6). The southwesterly flow associated with the summer monsoon and a continental anticyclone over Asia maintain a Mei-yu front along the South China coast (Figure 6, left panel). As the continental high moves eastward, the front migrates southward (Figure 6, middle panel). When the high moves out of the Asia mainland, a surge of northeasterlies then couples with southwesterlies to form a tropical depression (Figure 6, right panel).

Trade wind surges can also serve as a trigger, especially in the late season (Figure 7). At first, the trade wind maintains an area of cyclonic vorticity to its south (Figure 7(a) and 7(b)). A continental anticyclone moving out of the Asia mainland enhances the northeasterlies north of the area of cyclonic vorticity and increases the magnitude of the latter (Figure 7(c)) and finally spins up a TC (Figure 7(d)). A similar mechanism exists for genesis in the South China Sea associated with a surge of the northeast monsoon, again in the late season (Figure 8).

Another mechanism, though not very common, of TC genesis in the WNP is associated with the Tropical Upper Tropospheric Trough (TUTT) (Figure 9). If a cloud cluster and an associated low-pressure system (D) is positioned in such a way that its outflow can be enhanced by a cell (C) in the TUTT, this system can develop into a TC (Sadler, 1976).

A unique feature in the WNP is the monsoon gyre, which is a cyclonic circulation with a radius of over 1000 km. Occasionally, cloud clusters embedded in the periphery of this gyre can become TCs that rotate cyclonically around the center of the gyre (Figure 10(a)). In some instances, the gyre eventually becomes a large TC itself (Figure 10(b)).

The different environmental flow patterns for genesis have also been classified by Ritchie and Holland (1999), and more recently by Yoshida and Ishikawa (2013), into five types: monsoon shear line, monsoon confluence region, monsoon gyre, easterly wave, and preexisting TC. The first three types have been discussed in detail above. The easterly wave type was

considered by some researchers as part of the monsoon trough disturbance (see [Figure 3](#)) or a local vorticity maximum within the trade wind surge (see [Figure 7](#)). Indeed, [Ritchie and Holland \(1995\)](#) concluded that there is not enough evidence to support this type of genesis mechanism.

[Carr and Elsberry \(1997\)](#) first noted from barotropic model simulations that an anticyclone and cyclone pair could develop to the southeast of a relatively large TC through Rossby wave dispersion ([Figure 11](#)). [Ritchie and Holland \(1999\)](#), and later [Li and Fu \(2006\)](#), have shown that some TCs could indeed develop from a preexisting TC ([Figure 12](#)), although such formation does not occur very frequently as the TC has to have a certain size and the environmental flow also needs to have a good background relative vorticity ([Li et al., 2006](#)).

The prevalence of the monsoon trough throughout the peak season and the occurrence of the northeast monsoon explain why TCs can occur throughout the year in the WNP. The climatological distribution of the genesis locations ([Figure 13](#)) shows two maxima, one over the South China Sea and the other east of the Philippines. The former is mostly associated with the Mei-Yu front and northeast monsoon surges, while the latter with the monsoon trough and the trade wind surges. The monsoon trough shown in [Figure 4](#) and the

area of highest relative vorticity in [Figure 3](#) match very well with the locations of the peak values in genesis frequencies in [Figure 13](#), which suggests that in the WNP, the dynamic conditions are the determining factors in controlling TC genesis.

It should also be noted that the contours in [Figure 13](#) only go down to 1 (per 10 years). Some TCs actually form outside these contours, especially for very low-latitude genesis. For example, Typhoon Vamei (2001) formed at only 1.4° N , which is probably the lowest latitude at which a TC has ever formed ([Chang et al., 2003](#)).

The Fujiwhara Effect

During the peak season in the WNP (May to October), it is likely that more than one TC is present at any given time. Sometimes, they are in quite close proximity to each other and the circulation of one TC can affect the movement of the other. This is known as the Fujiwhara effect. The two TCs tend to rotate about a common 'center of mass.' [Lander and Holland \(1993\)](#) proposed a schematic in which the two TCs first approach each other, then go through a capture process and finally escape from each other, with each moving away from

Figure 14 Schematic showing the relative tracks of two TCs that are in close proximity to each other. The long-dashed track of the TC represented by the crosses and the continuous line connecting the filled circles representing the other TC show the 'escape routes' of the two TCs. The dotted track and the open circles represent the merger process. From Lander, M.A., Holland, G.J., 1993. On the interaction of tropical cyclone scale vortices. the other (Figure 14). In some instances, the TCs can merge during the capture process and become one TC. Whether or not the two TCs will merge or escape depends on the structure of the vortices (Chan and Law, 1995). While the tracks portrayed in Figure 12 are the relative ones, the actual tracks can appear to be very erratic.

Temporal Variations

As shown in Figure 2, the annual number of TCs in the WNP can have a large variation. An important factor in driving the variation on an interannual timescale is the occurrence of an El Niño or La Niña. In general, during an El Niño year, there tends to be more TCs and they form further to the southeast of the ocean basin. In fact, the area of TC genesis shown in Figure 11 east of 160° E is mainly contributed by those during El Niño years. On the other hand, TC genesis during La Niña years tends to occur in the northwest of the ocean basin. During El Niño years, because more TCs form further to the southeast, they have longer tracks over the ocean. As a result, they have a higher chance of becoming more intense. Therefore, the accumulated cyclone energy, defined as the sum of the squares of the MSW every 6 h of all TCs during a year, in an El Niño year tends to be higher than that in a La Niña year. It is useful to point out that the SST in the WNP during El Niño years is actually slightly lower than that during La Niña years (Chan and Liu, 2004), although it is still $>27^{\circ}\text{C}$. Thus, as discussed above, variations in the SST in the WNP do not control TC genesis there. Such a change in SST is actually in response to the SST conditions in the El Niño region.

On a longer time scale, there has been some evidence of the relationship between the stratospheric quasi-biennial oscillation (QBO) and TC activity variations. This relationship exists because of the change in the vertical wind shear during the different phases of the QBO, and hence the conditions for TC

genesis (Chan 1995). Both the number of TCs and the number of typhoons also exhibit multidecadal variations (Figure 2). These have been shown to be related to similar variations in the atmospheric flow patterns (Chan, 2008).

Summary

This article presents some particular features of TCs in the WNP, especially on the climatology, genesis mechanisms, the occurrence and movement of binary cyclones, and the relationship between TC occurrence and other atmospheric phenomena. No discussion is given on other aspects as they are not unique to this ocean basin and have been largely covered in Marks (2003). Although some statements on the possible variation in TC activity in relation to global warming have been made (Knutson et al., 2010), this topic is also not considered because studies on this topic are still ongoing.

Recently, some topics have received more attention such as changes in intensity as a result of the so-called eyewall replacement cycles that are more prevalent in the WNP, and the enhancement of rainfall around landfall as a result of the interaction between the TC and the environment such as the monsoon, especially when steep topography is present as in the case of Taiwan or the Philippines. In addition, the effect of warm ocean eddies in the WNP associated with the Kuroshio Current on the intensification of TC is also an important topic. All these are still under investigation.

Tropical Cyclones: Secondary Eyewall Formation

C-C Wu and Y-H Huang, National Taiwan University, Taipei, Taiwan

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

Secondary eyewall formation (SEF), a phenomenon often observed in intense tropical cyclones (TCs), is one of the key issues for TC research and forecasting as indicated by the widely documented findings related to the increase in storm size and short-term changes in TC intensity. This review article provides a comprehensive summary and discussions of current understandings of the plausible physical mechanisms for SEF in the literature. Provided with a favorable moist environment, a variety of internal dynamical processes for SEF have been proposed, such as the axisymmetrization process, energy accumulation through vortex Rossby wave activities, beta-skirt-induced energy cascade, unbalanced responses to boundary layer dynamics, and the balanced response to convective heating. The merits and caveats among different dynamical interpretations are discussed, while prominent unsolved SEF issues are also addressed to provide valuable guidance for future SEF research.

Background

Secondary eyewall formation (SEF) and the eyewall replacement cycle in tropical cyclones (TCs) have been widely documented by aircraft observations and high-resolution satellite imagery. Two concentric quasi-circular deep convective rings (inner and outer TC eyewalls) and a nearly cloud-free region (moat) located in between can be easily identified during the double-eyewall episode in TCs (Figure 1). For most such cases, the outer eyewall is established later, with characteristics similar to the inner eyewall. A local maximum swirling wind is often present in the outer eyewall, with the strong swirling wind region confined to the lower- or midtroposphere. Statistical analyses based on a 10-year data set (1997–2006) showed

that on average 70% of the Atlantic, 50% of the eastern Pacific, 40% of the Southern Hemisphere, and 80% of the western Pacific intense storms (maximum wind >120 kts) underwent at least one eyewall replacement cycle during their lifetime. Consistent statistical results were also obtained in recent studies, showing that SEF is a relatively common phenomenon in intense TCs. Because SEF, along with the subsequent eyewall replacement cycle, is often associated with temporary weakening of storms and concomitant increase in the extent of damaging gale-force winds, it remains as an important forecast priority for populated coastal communities and seagoing vessels over the open ocean.

Numerical simulations have been extensively applied to investigate SEF in many previous studies. Based on physical

Figure 1 Concentric eyewalls in Typhoon Talim (2005) near Taiwan. The figure on the left is the image retrieved from the Special Sensor Microwave Imager/Sounder sensor on the Defense Meteorological Satellite Program satellite at 1157 UTC 31 August 2005, available at the NRL (Naval Research Laboratory) Tropical Cyclone Page (www.nrlmry.navy.mil/sat_products.html). analyses and sensitivity experiments among numerical studies, a number of factors and mechanisms have been suggested as contributors to SEF. Section [Environmental Conditions](#) introduces the possible roles of various environmental conditions in SEF. As for the internal mechanisms responsible for SEF, there are a number of hypotheses proposed in the literature. Recent studies have found that the physical constraints applied to some hypotheses are not able to fully capture the physical processes involved in the life cycle of a real SEF event. Numerical simulations with more sophisticated physical processes, such as diabatic heating and boundary layer processes, suggested that some of the proposed hypotheses could not adequately address the key internal mechanisms of SEF in a real TC. The details of the aforementioned hypotheses are introduced and discussed in Section [Internal Mechanisms of SEF](#). Finally, Section [Vortex Rossby Waves](#) contains the concluding remarks upon the current understanding of SEF and proposes key issues to be further investigated.

Environmental Conditions

Environmental moisture is one of the major factors affecting TC intensity and structure. Numerical models with different designs have been adopted to study the impact of ambient relative humidity on SEF. In the axisymmetric model framework, high relative humidity is critical to SEF only if the hydrostatic assumption is applied. In contrast, full-physics model simulations showed that high environmental relative humidity is crucial to the formation of an outer eyewall in a TC. A plausible explanation is that high ambient humidity can provide more moisture and thus can enhance latent heat release in the vortex's outer core region, which likely provides a favorable environment for the expansion of storm size, the formation/intensification of rainbands, and even SEF. Another elucidation for the environmental influence on SEF is the sustained eddy angular momentum fluxes caused by interactions between a mature TC and its environment. If this TC–environment interaction is sufficiently influential in strength and space that gives rise to the Wind-Induced Air-Sea Heat Exchange (WISHE) process, a secondary eyewall likely establishes outside the primary eyewall.

Internal Mechanisms of SEF

Five internal mechanisms that have been frequently discussed in existing SEF studies are introduced and discussed in the subsections below, which are titled vortex Rossby waves (VRWs), axisymmetrization process, beta-skirt axisymmetrization (BSA) formation hypothesis, unbalanced boundary layer dynamics near the top of TC boundary layer, and balanced response to diabatic heating in a region of enhanced inertial stability.

Vortex Rossby Waves

Based on radar and satellite images, it has been found that disturbances with similar characteristics to Rossby waves are

often associated with rainbands in TCs. VRWs are thus coined for these eddy activities in TCs. Similar to Rossby waves in a planetary system, the dispersion relation for VRWs is closely related to the vorticity gradient of TCs. In a dry and barotropic framework, Montgomery and Kallenbach obtained an analytic solution of the stagnation radius for VRWs that propagate radially outward from the eyewall. It has then been proposed that the accumulation of energy near that stagnation radius can have impacts on the outer rainband structure and perhaps on the formation of secondary wind maximum. Houze and colleagues found that the model failed to simulate the eyewall replacement cycle of Hurricane Rita (2005), when the model resolution was reduced from 1.67 to 5 km. Meanwhile, they noticed that during Rita's eyewall replacement cycle, the small-scale features captured by the radar in the inner core region may be related to the VRWs' dynamics. The importance of high model resolution and the value of targeting small-scale structures in TCs are thus suggested for a better understanding of SEF and the subsequent eyewall replacement cycle. In contrast to consensus on the role of VRWs in TC rainbands, some recent studies argued the role of VRWs in SEF by using the model results with more sophisticated physical processes. Judt and Chen indicated that the near-zero potential vorticity (PV) gradient, subsidence, and straining effect which are already present prior to SEF are not conducive for VRWs' outward propagation, and thus provided reasonable doubt against the essential role of VRWs in SEF. Noting the ambiguous role of the eddy fluxes associated with VRWs in speeding up the tangential wind in the SEF region, Corbosiero and colleagues inferred that the outward propagation of the convectively coupled VRWs from the inner eyewall may act to redistribute PV and dump out moisture at the stagnation radius. It was thus suggested that VRWs make the active convection more prominent, but not to the extent that would directly cause SEF.

Axisymmetrization Process

Drawing from studies of vortex dynamics, the axisymmetrization process has been used to interpret the formation of vorticity ring outside the parent vortex in a two-dimensional barotropic model. Kuo and colleagues suggested that the primary vortex can axisymmetrize weak vorticity patches into a vorticity ring, provided that the primary vortex is strong enough and the two vortices are sufficiently close to each other. Nevertheless, recent studies noted that PV patches outside the eyewall can be of comparable magnitude to that in the eyewall region and have dipole structures in the real TC environment as simulated with more realistic physical processes (such as the moist convection). In particular, Moon and colleagues demonstrated that the interaction between the TC core vortex and the convection-induced small vorticity dipoles of considerable strength in two-dimensional flows does not lead to the formation of a coherent concentric vorticity ring. Thus the axisymmetrization process under a simplified two-dimensional incompressible flow appears insufficient for describing SEF in the real atmosphere. The critical role of the three-dimensional moist process in the maintenance of a vorticity ring has also been shown in recent studies.

Beta-Skirt Axisymmetrization Formation Hypothesis

Terwey and Montgomery presented a new moist-based BSA formation hypothesis as an intrinsic SEF mechanism. This hypothesis requires a region with sufficiently long filamentation time and moist convective potential, a sufficient low-level radial PV gradient (i.e., a beta skirt) associated with the primary swirling flow and the follow-up WISHE process. The long filamentation time and sufficient moist convective potential set the scene for a convectively favorable environment. The beta-skirt structure and WISHE process provide a dynamical pathway to SEF. Applying the two-dimensional turbulence theory to the problem of SEF in a rotating TC environment, the theme of the BSA hypothesis is that the upscale energy cascade tends to occur on the beta skirt. Following this pathway, eddy kinetic energy associated with the sporadic convective cells outside the primary eyewall may be injected into the tangential direction and enhance local low-level jets (axisymmetrized into the mean tangential flow) on the skirt of the vortex's PV profile. Once the low-level jet strengthens substantially, it could further intensify by coupling with the boundary layer through a wind-induced moisture feedback process such as WISHE and may ultimately lead to SEF. The timescale of this energy cascade process and the width of the corresponding jet can be evaluated by the values of its PV gradient. Though simulated results in relevant studies showed consistency between the evaluated and simulated jet width, direct supporting evidence for the described energy upscale process needs to be further investigated.

Unbalanced Boundary Layer Dynamics near the Top of TC Boundary Layer

A deeper understanding of the underlying dynamics of SEF has been proposed in two recent companion studies, based on the two mechanisms for the spin-up of mean tangential winds in single-eyewall TCs. Both mechanisms are associated with the radial advection of absolute angular momentum ($M = fr^2/2 + rv$). The first mechanism is for the spin-up above the boundary layer where M is materially conserved. The convergence of M is enhanced by the negative radial gradient of a diabatic heating rate associated with convective structures in a TC. This mechanism has been addressed in many extant studies. It explains why the vortex expands in size in terms of axisymmetric balanced dynamics, wherein the vortex is well approximated by gradient wind and hydrostatic balance. The second mechanism is related to the spin-up process within the boundary layer and is considered important in the inner core region of the storm. Although M is not materially conserved here, tangential winds can still be enhanced if the boundary layer inflow is sufficiently large to bring the air parcels to the small radii with minimal loss of M to friction. The boundary layer flow is coupled to the interior flow via the radial pressure gradient at the top of the boundary layer, but the spin-up of a vortex is ultimately tied to the dynamics of the boundary layer where inflow is prevailing and the swirling wind is not in gradient wind balance over a substantial radial span.

By assimilating T-PARC (THORPEX Pacific Asian Regional Campaign) data (particularly aircraft reconnaissance and

surveillance observations) into the Weather Research and Forecasting (WRF) model based on ensemble Kalman filter data assimilation, Wu and colleagues constructed a model/observation-consistent and high-spatial/temporal resolution data set for Typhoon Sinlaku (2008) in the first part of the two companion works. The key features related to the horizontal broadening of low-level troposphere swirling flow and intensification of boundary layer inflow over the outer region are identified before SEF (Figure 2). These two important features are consistent with the two mechanisms highlighted for the spin-up of single-eyewall TCs and set the scene for a progressive boundary layer control pathway to SEF.

As the second part of the two companion papers, Huang and colleagues addressed the association between increases in storm size and SEF from the axisymmetric aspect. The findings point to collective structural changes in the outer core region of a mature TC, which ultimately culminates in the formation of a secondary eyewall. The sequence begins with a broadening of the low-level tangential wind field associated with the intensification of the eyewall that can be demonstrated by the balanced response above the boundary layer (the first mechanism mentioned above). Due to the presence of surface friction, boundary layer inflow increases underneath the broadened swirling wind, and becomes large enough to enhance the swirling circulation within the boundary layer (the second spin-up mechanism). This rapid increase in tangential winds near the top of the boundary layer breaks the gradient wind balance, leading to the local development of supergradient winds, which decelerate the inflow air parcels and impede them from moving inward (Figure 3). This process leads to the transition outside the primary eyewall from sporadic and/or weak convergence in the lower troposphere to a well-defined convergence zone concentrated within and just above the boundary layer. The progressive increase of supergradient forces thus continuously provides a mechanical mean for high enthalpy air to erupt from the boundary layer. Given the dynamically and thermodynamically favorable environment for convective activities, the progressive response of the unbalanced boundary layer flow to an expanding swirling wind field and the positive feedback loop in between are demonstrated to be an important mechanism for concentrating and sustaining deep convection in a narrow supergradient-wind zone collocated with the SEF region. The pathway to SEF can be summarized in a schematic diagram (Figure 4), elucidating the chain of TC structure changes and associated physical processes and feedbacks.

The SEF paradigm advanced in these two companion works is attractive on physical grounds because of its simplicity and consistency with the three-dimensional numerical simulations presented. While understanding the importance of the balanced response (cf [Balanced Response to Diabatic Heating in a Region of Enhanced Inertial Stability](#) subsection), this paradigm peculiarly highlights the critical role of unbalanced dynamics in SEF. Two recently published studies also investigated the impact of boundary layer dynamics on SEF from different perspectives. Concerning the asymmetry associated with rainbands that prevail prior to SEF, Qiu and Tan reexamined this SEF paradigm in an asymmetric framework. The sequence of structure changes

within and just above the boundary layer preceding SEF and the corresponding dynamical pathway to SEF found in their simulation showed supporting results for the presented paradigm. Meanwhile, Wang and colleagues investigated the depth-integrated boundary layer flow, and demonstrated results that generally agree with the SEF pathway proposed in this paradigm.

The presented progressive boundary layer control on SEF also implies that the boundary layer scheme and its coupling to the above atmosphere need to be adequately represented in numerical models to improve the understanding of SEF, as well

as the accuracy of SEF forecasts, including the timing and preferred radial intervals.

Balanced Response to Diabatic Heating in a Region of Enhanced Inertial Stability

As discussed in the previous subsection, responses of transverse circulation to a heating/momentum source/sink framed in the thermal wind balance relationship known as Sawyer–Eliassen equation, has been applied to understand the evolution of the mean swirling circulation in idealized vortices in many extant

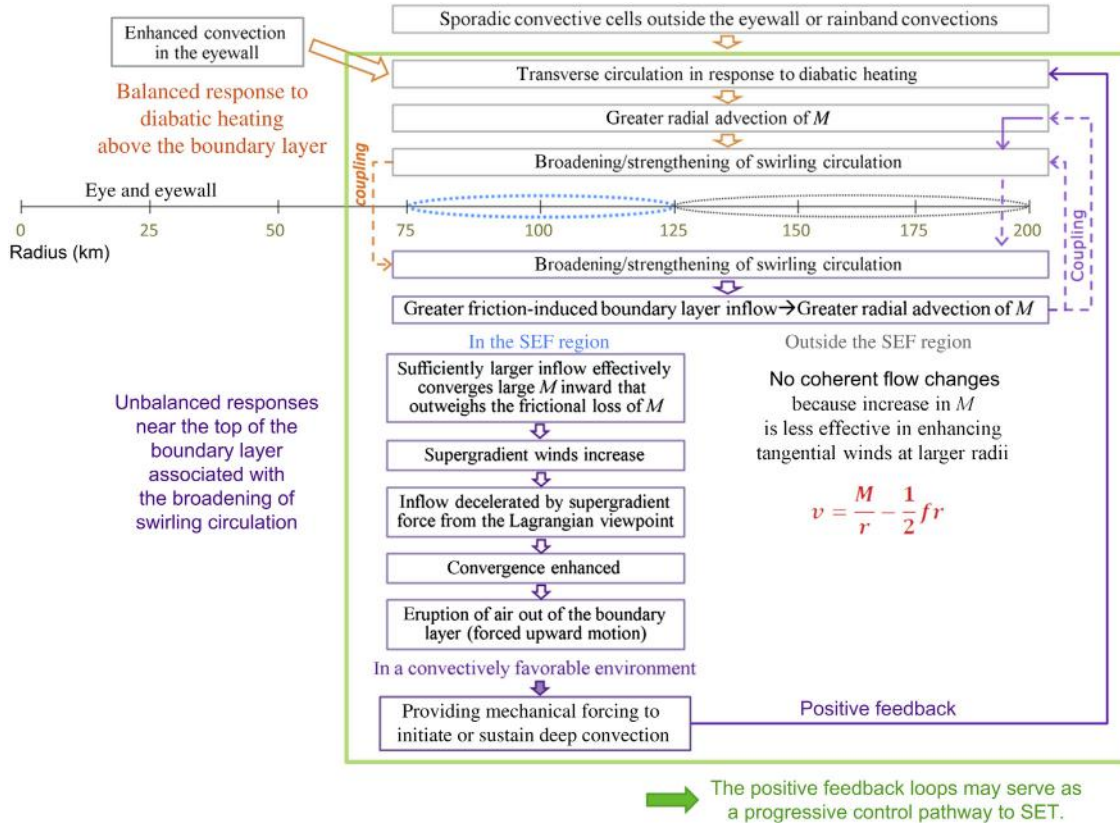

Figure 4 The schematic diagram describing the SEF paradigm introduced in Section [Unbalanced Boundary Layer Dynamics near the Top of TC Boundary Layer](#). Orange arrows refer the balanced response to diabatic heating, which is constrained by the thermal wind relationship. Purple arrows indicate the unbalanced dynamics, characterized by the development of supergradient wind near the top of boundary layer and a chain of corresponding structure changes. Dashed lines stand for the coupling relationship between the boundary layer and the free atmosphere aloft. The positive feedback loop enclosed by the green box is shown as a progressive control pathway to SEF.

studies. Using an idealized, cloud-resolving WRF simulation, Rozoff and colleagues revisited the balanced dynamics for SEF from the axisymmetric aspects. An expansion of kinetic energy (or enhanced inertial stability) is found prior to the SEF in their WRF simulation, a feature consistent with the presence of beta-skirt structure and the expansion of tangential winds in previous studies. The impact of this enhanced kinetic energy and diabatic heating on SEF was further investigated using an axisymmetric linearized, nonhydrostatic model (a balanced vortex model quite similar to the Sawyer–Eliassen model). Given the axisymmetric tangential wind and temperature profiles from the WRF model output, this simple model depicts how the transverse circulation responds to diabatic heating and surface friction prescribed also from WRF. The diagnosed results share similarity with the mean vortex structure in the WRF simulation in a number of ways, and suggest that the sustained diabatic heating along with the broadening wind outside the primary eyewall contributes the most to the enhancement of tangential winds in the SEF region.

Concluding Remarks

This article revisits favorable conditions and mechanisms that have been suggested for SEF in the existing studies.

Regarding the environmental control of SEF, model initial relative humidity has been identified critical for the increase of storm size and the subsequent SEF in recent studies using sophisticated numerical models. On the other hand, a variety of different approaches have been proposed as the internal mechanisms of SEF, including (1) axisymmetrization of prescribed/present outer vorticity patches, (2) the accumulation of eddy kinetic energy associated with VRWs near their stagnation radii, (3) the energy cascade process over the beta skirt of the TC vortex in a convectively favorable condition and subsequent positive feedback provided by WISHE (BSA hypothesis), (4) unbalanced response (i.e., the generation of supergradient wind, and its impact on the transverse circulation) to the expanding winds, and (5) balanced response of transverse circulation to diabatic heating over the area with enhanced inertial stability. Particularly noteworthy is that the broadening tangential wind (the beta-skirt structure and enhanced kinetic energy basically indicate a similar structure as well) furnishing the pathway to SEF is a vital process among different internal dynamical interpretations of SEF. Various conditions and mechanisms have been suggested for the establishment of such a skirted vortex structure, including higher environmental relative humidity or diabatic heating associated with outer rainbands, the initial vortex size/shape, concurrent

storm intensity, convective heating in an intensifying storm, and radially outward propagating VRWs.

Although recent advances of the unbalanced and balanced dynamics in TCs with double eyewalls appear promising in interpreting SEF from the axisymmetric perspective, the quantitative impacts of these aspects on SEF and their mutual feedback remain to be further investigated. While the symmetric dynamics has been shown to play a critical role in SEF, how the asymmetric components (e.g., spiral rainbands and sporadic convective cells in the vortex's outer core region) influence SEF also needs further studies to gain more comprehensive understanding. While the environmental conditions are relatively well understood and better presented in the observations and numerical models, discoveries are also being made on more uncertainties associated with the evolution of a TC vortex and the accompanied convective-scale features. More TC observations and further investigation on the internal vortex dynamics are thus required to better present the corresponding physical processes (e.g., microphysics, boundary layer dynamics, etc.) in numerical simulations of SEF, as well as the whole TC life cycle.

Introduction

During 1877 and 1878 much of China was struck by famine, due to a severe drought. More than nine million people perished. In India, at the same time, more than eight million deaths were attributed to famine also caused by a drought. In many districts, a quarter of the population died. Drought in the same period also caused crop failures, scarcity of food or even famine, in north-eastern Brazil, Egypt, Indonesia, Fiji, Australia, and southern Africa. In other parts of the world, including Ceylon, the Pacific coast of South America, and Tahiti, many lives were lost from unusual storms or extended periods of heavy rain and flood. The El Niño Southern Oscillation, a major pattern of climate variation, links these climatic extremes in different parts of the world; the first major El Niño event for which good records exist was the 1877 event. Subsequent El Niño events have often reproduced the pattern of climate extremes and societal impacts observed in the 1877 event. We now use the phenomenon to make predictions of seasonal climate variations in many parts of the world.

How Was the El Niño Southern Oscillation Discovered?

The famine in India in 1877 led to the first scientific attempts to understand and predict monsoon failures and drought, and eventually to the mapping of the El Niño Southern Oscillation.

Henry Blanford, then the head of the India Meteorological Department, noticed that atmospheric pressures were higher than usual over India during the drought. He advised meteorologists in other parts of the British Empire of this and asked them about atmospheric pressures in their colonies.

Blanford's message reached the South Australian Government Astronomer and Meteorologist, Charles Todd, who noticed that Australian atmospheric pressures were also high, and that the country had been experiencing a drought at the same time as India. When another drought struck Australia in 1888, Todd realised that India and Australia often experienced drought at the same time. This synchronism of drought in the two countries is part of the suite of long-range connections (teleconnections) between climate fluctuations in different parts of the world that we now call the Southern Oscillation. For the next few decades, several meteorologists around the world were occupied in mapping these teleconnections into a coherent pattern. Sir Gilbert Walker was the most prominent among these mappers, and it was he who named the teleconnection patterns the Southern Oscillation. Walker used these teleconnections to develop statistical systems for forecasting climate anomalies in many parts of the world.

In the middle of the twentieth century, interest in the Southern Oscillation declined. This was partly because the focus of atmospheric scientists shifted to shorter time scales, as computer models exhibited their ability to forecast weather. A second reason for the decline in interest was the absence of

any theory explaining the teleconnections or the long time scale of the phenomenon. In the early 1960s, Hendrik Berlage and Jacob Bjerknes separately demonstrated that the El Niño and the Southern Oscillation were related. The term El Niño originally (at the end of the nineteenth century) referred to the annual weak warm current that runs southward along the coast of Peru and Ecuador at the end of the year. Subsequently, scientists applied the term to denote the occasional large warmings that occur every few years and result in major disruptions to the region. Bjerknes developed a theory for how this essentially tropical phenomenon could affect climate at higher latitudes. This step, along with the severe ecological and human consequences of the major El Niño episodes of 1972 and 1982, revived scientific interest in the study of interannual climate variations and their prediction. The phenomena are now jointly referred to as the El Niño Southern Oscillation, reflecting their close relationship.

What Causes the El Niño Southern Oscillation?

The joint name El Niño Southern Oscillation, is appropriate because ocean–atmosphere interaction is the cause of the phenomenon. Easterly winds over the eastern and central equatorial Pacific cause oceanic ‘upwelling’ (cooler subsurface waters being lifted to the surface) along the Equator. Southerly winds in the eastern Pacific also cause upwelling along the South American coast. As a result, the Pacific Ocean is usually cooler in the east than in the west by several degrees.

At tropical latitudes, heavy rains accompany warm oceans, so the warm west Pacific (including Indonesia and New Guinea) is a heavy rainfall region, while the cooler east Pacific receives little rainfall. [Figure 1](#) shows the mean sea surface

temperatures for December. The relative coolness of the east Pacific, compared to the west equatorial Pacific is evident.

This is the ‘average’ situation, but during an El Niño the ocean temperature gradient from one side of the Pacific to the other weakens, and the easterly winds weaken. Droughts occur in the west (around the Indian Ocean and the west Pacific) associated with cooler than normal ocean temperatures, while the unusually warm waters in the east bring heavy rains and floods to the normally arid Pacific coast of South America. [Figures 2 and 3](#) show the strong warming of the east equatorial Pacific that took place during the 1997/98 El Niño. [Figure 2](#) shows the sea surface temperatures during December 1997, at the peak of the El Niño. Warming in the east Pacific at that time had almost completely removed the east–west temperature gradient. The east equatorial Pacific warming of about 5°C is shown in [Figure 3](#), which exhibits the anomalies (deviations from climatology).

How does an El Niño start? A small change in the usual sea surface temperature pattern can produce a change in the winds along the Equator. In turn, these wind changes affect the currents that change the pattern of sea surface temperatures even more. This process continues, with ocean temperatures affecting winds that affect currents that, in turn, affect ocean temperatures. One important change is related to bursts of westerly winds in the western Pacific. These can trigger eastward-moving ocean disturbances that cause the thermocline (the transition layer between warm surface water and cooler, lower waters) to deepen in the east Pacific. This means that it is harder for the upwelling to cool the surface (because the upwelled water is now coming from the upper, warmer layer), so the east Pacific warms. Eventually, in the biggest El Niño events, the difference in temperature between the west and east equatorial Pacific Ocean can disappear altogether. As a result of

Figure 1 Climatological sea surface temperature for December. Analysis from Bureau of Meteorology, Australia.

Figure 2 Sea surface temperature for 15–21 December 1997. Analysis from Bureau of Meteorology, Australia.

Figure 3 Sea surface temperature anomalies (deviations from climatology) for 15–21 December 1997. Analysis from Bureau of Meteorology, Australia.

these major changes in sea surface temperature and the surface winds, the whole pattern of climate and atmospheric circulation across the Pacific and Indian Oceans, and the surrounding continents, is disrupted, with droughts in normally wet areas and heavy rains over normally arid regions.

The changes associated with the El Niño often persist for about a year and then usually collapse quite quickly.

Sometimes a mirror-image pattern of climate disturbances, with flooding in Australia, India, Indonesia, northeast Brazil, and dry conditions on the Pacific coast of South America, follows. This set of conditions is called La Niña. La Niña episodes also usually last about a year or so.

As alluded to earlier, the atmospheric variations associated with El Niño and La Niña events are called the Southern

Oscillation. This name derives from the observation (dating back to the time of Blanford and Todd) that, during an El Niño, atmospheric pressures are usually higher than normal over Australian and the Indian Ocean and lower than normal in the southeast Pacific. During the opposite phase, the La Niña, the pressure anomalies are reversed. So, in a sense, the atmosphere acts like a seesaw, with high or low pressures on either side of the Pacific.

We can monitor this seesaw in atmospheric pressure with the Southern Oscillation Index or SOI. This is the standardized difference in pressure between Tahiti and Darwin. When the SOI is negative, pressures are high over the Australian region and relatively low in the southeast Pacific. This is an indication that the Trade Winds are weak across the Pacific, and these weaker winds result in warm east equatorial Pacific sea surface temperatures – an El Niño. Figure 4 shows time-series of the Darwin mean sea level pressure and sea surface temperatures in the ‘cold tongue’ of the east equatorial Pacific (180°–90°W, 6° N–6°S). The close relationship between the atmospheric pressure on one side of the Pacific and sea surface temperatures on the other side is clear, as is the tendency for El Niño and La Niña events to last about 12 months.

This tendency to last about 12 months means that the climate effects related to the El Niño Southern Oscillation are strongly persistent and thus predictable. This persistence is

greater during the second half of the calendar year, because El Niño episodes tend to start around March–May and finish around the same time a year later. Thus, if an event is under way by midyear it is likely to persist through the second half of the year. This means that climate anomalies usually associated with the presence of an El Niño at this time can often be predicted well in advance. The tendency for El Niño events to start around March–May is illustrated in Figure 5, which shows east equatorial Pacific sea surface temperature anomalies during the major events of the second half of the twentieth century. In each of the five events, sea surface temperature anomalies in the east equatorial Pacific were relatively low at the start of the year, and then increased rapidly from about March, reaching a peak near the end of the calendar year. The temperature anomalies subsequently weakened over the next few months.

What Areas Does the El Niño Southern Oscillation Affect?

The pattern of climate anomalies seen in the 1877 El Niño tends to be repeated each time an El Niño occurs. The typical pattern of rainfall anomalies associated with an El Niño is shown in Figure 6. The figure indicates, for each area

Figure 4 Time series of annual mean Darwin mean sea level pressure (MSLP) and sea surface temperature in the area 180°–90° W, 6° N–6° S ('Cold Tongue Index', CTI). Darwin data from Bureau of Meteorology, Australia. CTI data from Todd Mitchell, JISAO, University of Washington.

Figure 6 Schematic of areas with a consistent precipitation signal associated with El Niño events. For each region the months are shown during which it is consistently wetter or drier than normal. In each region the list of months begins in the initial year of the El Niño (year=0). Reprinted with permission from Cambridge University Press of Trenberth, K.E., 1991. in Glantz, et al., 1991.

consistently affected by the El Niño, the months in which the anomalies are most consistent. The pattern of precipitation anomalies associated with the other extreme of the El Niño Southern Oscillation, the La Niña, is essentially the opposite of that depicted in Figure 6 (i.e., where drier than normal conditions are usually experienced during an El Niño, then wetter than normal conditions can be anticipated during a La Niña episode).

The El Niño Southern Oscillation also affects temperatures in some parts of the world. Thus in December–February at the peak of an El Niño, temperatures are usually above average throughout central and southern Africa, southern Asia, and the western Pacific, Canada, and the Pacific coasts of North and South America. The south-east of the United States tends to be cooler than average. Severe frosts can occur in places where drought accompanies an El Niño episode, such as the highlands of Papua New Guinea and inland eastern Australia.

The El Niño Southern Oscillation also affects tropical cyclones and some other weather and climate extremes. Figure 7 is a time-series of the SOI and of the number of tropical cyclones around Australia. When an El Niño is under way (i.e., when the SOI is strongly negative), fewer than normal tropical cyclones are observed around Australia. Similarly, Atlantic hurricane activity is reduced during El Niño episodes. On the other hand, tropical cyclones are more frequent than usual in the east Pacific during these episodes.

Prehistoric Behavior of the El Niño Southern Oscillation

Instrumental records relevant to the study of the El Niño Southern Oscillation are available back into the late nineteenth century. The study of El Niño episodes prior to this depends on

Figure 7 Time-series of the Southern Oscillation Index (SOI) (○) and the number of tropical cyclones in the Australian region (0°–15° S, 105°–165° E) (□). Data from the Bureau of Meteorology, Melbourne, Australia.

documentary records, and paleoclimatic (proxy) records. Documentary evidence of heavy rains and floods on the Pacific coast of South America (always associated with El Niño episodes during the instrumental era) are available from the sixteenth century. Comparisons of the dates of heavy rains and floods in South America with dates of droughts in other parts of the world have confirmed that the El Niño Southern Oscillation has been operating for at least hundreds of years. The teleconnections between droughts and floods in these various parts of the world have been similar throughout these five centuries, reflecting the effects of the El Niño Southern Oscillation throughout this period.

Paleoclimatic data, from corals, ice cores in glaciers, tree rings, and marine and lacustrine sediments also provide information regarding the occurrence of El Niño episodes prior to the instrumental period. This evidence, although not conclusive, suggests that El Niño episodes have been occurring for at least several thousand years.

The El Niño Southern Oscillation in the Recent Past

The prominence of the El Niño Southern Oscillation has varied through the instrumental period. Very strong El Niño episodes occurred in the first quarter of the twentieth century, with only relatively infrequent, and weak, events in the period 1925–1950. After 1950, more intense El Niño and La Niña events were observed. Since the mid-1970s, there appears to have been a shift toward more frequent, or stronger, El Niño episodes, with La Niña episodes becoming relatively infrequent. Some analyses suggest that this behavior is very unusual, given the (admittedly short) historical record.

Future Observations of the El Niño Southern Oscillation

For most of the period during which the El Niño Southern Oscillation has been monitored and studied, observations

originally intended for other purposes have been the main source of information. Atmospheric pressure, rainfall, and temperature observations originally taken for the purposes of weather recording and forecasting, or to determine the ‘average’ climate, have been used in studies of how the phenomenon affects climate variations around the globe. Sea surface temperatures recorded by merchant and other ships have been the main source of information about the ocean variations associated with the El Niño. In recent decades, however, new and improved observations, specifically designed for climate studies, have been initiated. These include satellite observations of rainfall and sea surface temperature and sea-level, moored buoys monitoring the ocean and atmosphere in critical parts of the ocean, and subsurface analyses of the ocean thermal structure. The analysis of these new data is in its infancy, but the data have already enhanced our ability to monitor, understand, and predict the El Niño Southern Oscillation.

Introduction

The El Niño Southern Oscillation (ENSO) is a spectacular, planetary-scale climate phenomenon that is inherently caused by interactions between the atmosphere and the ocean. Historically, El Niño refers to unusually warm ocean temperatures that occur every 2–7 years around Christmas time along Peruvian coast, extending into equatorial eastern and central Pacific Ocean. The Southern Oscillation, named by its discoverer – Sir Gilbert Walker – on the other hand, refers to a ‘seesaw’ of the atmospheric pressure between the Pacific and Indian Oceans. It was not until the seminal work of Jacob Bjerknes in the late 1960s that scientists realized that these two phenomena are intimately linked. The acronym ENSO has now been widely used to describe this fascinating interannual climate fluctuation, emphasizing the inherent ocean–atmosphere coupling.

Although the origins of ENSO lie in the tropical Pacific, the impact of ENSO is global, owing to planetary waves of the atmosphere that redistribute vorticity from tropics to extra-tropics. The ‘teleconnection’ of ENSO can disrupt weather patterns around the globe. For this reason, ENSO has been recognized as the most important climate phenomenon at interannual timescales.

Theoretical understanding of the development and evolution of ENSO, and of underlying dynamical mechanisms for its irregular oscillation at interannual timescales, goes beyond the boundary of traditional dynamical meteorology and oceanography, because it requires knowledge about how the tropical atmosphere responds to sea surface temperature changes; how the equatorial ocean adjusts to changes in winds; and how various feedback loops between the atmosphere and ocean operate and interplay. This understanding provides the theoretical basis for the development of ENSO prediction systems, which are critical for operational seasonal-to-interannual climate forecasting.

The Southern Oscillation and Walker Circulation

From an atmospheric perspective, the Southern Oscillation can be viewed as a perturbation about a thermally driven east-to-west circulation of the tropical atmosphere across the Pacific Ocean. This circulation, known as the Walker Circulation, is caused by the sharp contrast in sea surface temperature across the tropical Pacific Ocean. The western tropical Pacific contains the warmest regions of the world’s ocean, known as the Western Pacific Warm Pool, where the sea surface temperature is above 28°C. In contrast, the eastern equatorial Pacific features relatively cold ocean surface waters, extending from

South America coasts westward along the Equator. This is known as the Eastern Equatorial Pacific Cold Tongue, where the sea surface temperature is 5–10°C colder than the surface water of the warm pool. The warm water in the western Pacific creates low surface pressure, which causes moisture-laden air to converge into the region. The air rises and the moisture condenses in strong convective events, resulting in widespread cloudiness and heavy precipitation. The rising air descends from the upper troposphere to the surface in the Eastern Equatorial Pacific Cold Tongue as dry air. Cool temperatures result in relatively high surface pressure, divergent flow, and little rainfall. These motions – rising in the west, sinking in the east – are connected through easterly Trade Winds near the surface and a westerly wind aloft, forming the Walker Circulation.

Fluctuations in the position and intensity of the Walker Circulation cause the Southern Oscillation. When the sea surface temperature in the eastern Pacific is warmer than normal, such as during El Niño years, the low atmospheric pressure center normally situated in the Western Pacific Warm Pool moves eastward, bringing along with it the rising moist air and heavy precipitation. As a result, the east–west pressure difference across the Pacific is reduced and the easterly Trade Winds are weakened. This produces a weak Southern Oscillation (a negative phase). By the same token, the strength of the Southern Oscillation is enhanced (a positive phase) when the sea surface temperature in the eastern Pacific falls below normal. This sensitivity of the tropical atmosphere circulation to sea surface temperature fluctuations is one of the key elements of ENSO physics.

A secondary process that contributes to equatorial trade wind fluctuations involves the so-called Hadley circulation, a meridional overturning cell spanning the tropical Pacific (and the global tropics). This circulation consists of a rising branch, concentrated in a narrow zone generally north of the Equator, known as the intertropical convergence zone (ITCZ), and sinking motion, with increasingly strong surface easterlies both north and south of the ITCZ. During El Niño, as the equatorial surface temperature warms, the ITCZ and attendant Hadley circulation shift equatorward, leading to a reduction of equatorial easterly winds, beyond that associated with the Walker Circulation.

Many of the essential features of the Walker Circulation (and Hadley circulation) can be captured by a simple physical model in which the tropical atmosphere is assumed to be forced by a diabatic heating source and subject to simple dissipation of momentum and heat (with common decay rate r of order of 1–2 days). The diabatic heating is largely induced by latent heat released by the rising moist air over the warm ocean, and this can be approximated as a function of sea surface

temperature. Assuming that the vertical structure of the diabatic heating is fixed and has a simple structure with a single maximum at midlevels decreasing to near zero at the surface and upper levels (which approximates to the heating field produced by cumulus convection in the tropics), then the entire circulation pattern in the vertical projects primarily onto the so-called first baroclinic mode of the tropical atmosphere, and the horizontal motions at each level obey a two-dimensional set of equations (the so-called shallow water equations). Therefore, the forced solution of the shallow water equation can give the first-order approximation of the Walker Circulation. In the region of heating, for example, in the Western Pacific Warm Pool, the diabatic heating gives rise to a vertical velocity which causes the lower atmosphere to expand and the vortex to stretch. To conserve potential vorticity, the surface air parcels must move poleward to generate cyclonic vorticity in order to balance the ambient vorticity change. The diabatic heating also excites planetary waves which induce remote response outside the region of heating. Of particular interest is a Kelvin wave propagating eastward at a speed c . It gives an easterly wind symmetric about the Equator which decays at a rate of r/c per unit distance. This easterly wind is reminiscent of the Trade Winds along the equatorial Pacific as a part of the Walker Circulation. To the west of the forcing region, there are Rossby waves which cause the cyclonic flow to expand westward. The simple atmospheric model gives an analytical expression linking changes in the equatorial Trade Winds to changes in sea surface temperature through its effect on the diabatic heating of the atmosphere.

Equatorial Ocean Adjustment

From an oceanic perspective, changes in sea surface temperature associated with El Niño can be understood in terms of an equatorial ocean response to changes in the Trade Winds. Under normal conditions, an easterly wind stress supplied by the Trade Winds in the central and eastern Pacific acts on the ocean surface. This stress is balanced by friction and the Coriolis force, resulting in poleward surface flow in either hemisphere and thus upwelling in the eastern equatorial Pacific and South American coast. The westward winds also 'push' the relatively warm surface water westward, bringing cold subsurface water to the ocean surface and lifting the so-called thermocline of the ocean in the east. The thermocline represents a band of water within which the temperature changes rapidly with depth, thereby separating the warm upper ocean from the cold deep ocean. The Trade Winds thus cause the thermocline to shoal from west to east across the equatorial Pacific Ocean, maintaining the warm pool in the west and the cold tongue in the east. During a negative phase of the Southern Oscillation, the easterly Trade Winds are weaker than normal, which reduces the upwelling in the east, deepens the thermocline, and causes the sea surface temperature to rise. An El Niño is produced! The opposite occurs during a positive phase of the Southern Oscillation, when the Trade Winds are strengthened.

The close relationship among Trade Winds, thermocline, and sea surface temperature results from the rapid adjustment of the equatorial ocean. Because the Coriolis force vanishes at the Equator, there is a wave guide along the Equator, where

a variety of waves are trapped to within a few degrees to either side of it in the ocean (and a few tens of degrees in the atmosphere). Two types of waves, the equatorial Kelvin and Rossby waves, are of particular importance. Kelvin waves are special gravity waves that propagate eastward with a speed of approximately $2\text{--}3\text{ m s}^{-1}$, and can travel across the Pacific Ocean in 2 months or so. Rossby waves are planetary vorticity waves that propagate westward at a rate of about $0.6\text{--}0.8\text{ m s}^{-1}$, and can travel across the Pacific in 6–7 months. Both these waves propagate at a rate that is faster by an order of magnitude or more than the planetary waves in extratropical oceans. For this reason, equatorial oceans adjust much more rapidly than extratropical oceans in response to changes in the wind stress forcing. Therefore, at interannual timescales, the zonal gradient of the equatorial thermocline and overlying Trade Wind stress are approximately at balance.

The response of the equatorial ocean to changes in the zonal wind stress can again be modeled in terms of a shallow water model. Here, the ocean is approximated as a two-layer fluid system with a thin, warm layer on top of a deep, cold layer. The interface between the two layers represents the ocean thermocline which has an average depth of approximately 150 m in the equatorial Pacific. Motions of upper layer and the interface obey shallow water equation subject to wind stress forcing. The steady-state solution is very nearly a balance between the zonal wind stress and zonal gradient of thermocline. When a change in the trade wind occurs, the ocean is subject to an anomalous zonal wind stress forcing. A typical wind stress anomaly associated with the Southern Oscillation has a spatial structure that has the largest amplitude in the western central equatorial Pacific and decays away from the Equator. Because of the nonuniform spatial structure, off-equatorial wind stress curl is generated. The oceanic response to such an anomalous wind stress forcing in the shallow water system takes place in two stages: first, an equatorial Kelvin wave is excited by the strong wind stress anomaly at the Equator, propagating eastward and causing changes in depth of the thermocline; and sea surface temperature in the eastern equatorial Pacific upon its arrival. At the time when the Kelvin wave is excited, Rossby waves of opposite sign to the Kelvin wave are also generated by the off-equatorial wind stress curl associated with the wind stress anomaly. These Rossby waves propagate westward and reflect at the western boundary as a second Kelvin wave – now with the opposite sign to the first Kelvin wave – and thus work against the effect brought by the first Kelvin wave in the eastern equatorial Pacific with a time delay. It is this delayed response in the eastern equatorial Pacific produced by the same wind stress forcing that provides the oceanic 'memory', another key element of ENSO physics.

Coupled Dynamics

If the atmosphere and ocean were decoupled, then small perturbations in either the sea surface temperature or the winds would fade quickly away because of dissipation in the oceans and atmosphere. In reality, the tropical atmosphere and equatorial ocean in the Pacific Ocean are tightly coupled, because of the sensitivity of the atmospheric response to sea surface temperature changes and the rapid adjustment of the

equatorial ocean to changes in winds. Therefore, a modest change in either the equatorial sea surface temperature or the Trade Winds can trigger a chain reaction in the coupled ocean–atmosphere system, involving a positive feedback between the atmosphere and the ocean.

Bjerknes Feedback Mechanism

The key ingredients of this positive feedback were first pointed out by Bjerknes. Consequently, the mechanism has become known as the Bjerknes hypothesis. Imaging that there is initially a weak westerly wind anomaly along the Equator that causes the Trade Winds to weaken. From the equatorial ocean adjustment discussed above, a weak warm sea surface temperature anomaly is expected to occur in the eastern equatorial Pacific, owing to deepening in the thermocline depth and weakening in equatorial upwelling. Because the tropical atmosphere is sensitive to changes in sea surface temperature, the small increase in sea surface temperature in the east will tend to move atmospheric convection eastward, reduce the diabatic heating in the west, and weaken the Walker Circulation. This causes a further weakening of the Trade Winds, which in turn leads to a further warming in the eastern equatorial Pacific, and so on. Key elements of this feedback loop are illustrated in Figure 1. The Bjerknes hypothesis marks the beginning of the formation of modern ENSO theory.

Figure 1 The Bjerknes hypothesis describes a positive feedback between the ocean and atmosphere in the equatorial Pacific: a weakening in the Trade Winds causes a warming in the eastern Pacific through a deepening in the thermocline and a weakening in the upwelling, which in turn leads to a further weakening in the Trade Winds. Reproduced from Chang, P., Battisti, D.S., 1998. The physics of El Niño. *Physics World* 11, 41–47.

Coupled Modes

A quantitative understanding of the coupled dynamics can be gained by formulating a simple coupled ocean–atmosphere model, such as the two shallow water systems described above. A stability analysis can then be applied to the coupled system to obtain a set of modes which describe how the coupling between the ocean and atmosphere can modify free oceanic and atmospheric wave modes in a wide range of dynamical parameter space. Such an analysis leads to the discovery of a new breed of ‘wave modes’, with characteristics that depend on the strength of the air–sea feedback and the adjustment timescale of the ocean. For a weak air–sea feedback, the adjustment time of the ocean is much faster than that imposed by the weak air–sea feedback. Therefore, the free waves are not significantly influenced by the air–sea feedback and the coupled modes behavior similar to those of free waves. For a strong air–sea feedback, the adjustment time of the ocean is much slower than that imposed by the strong air–sea feedback. The coupled modes depend critically on the air–sea feedback, but are less influenced by the oceanic adjustment. In this limit, the coupled modes behave quite differently from the free ocean waves and tend to be more unstable because of the strong influence of the positive air–sea feedback.

In between these two extreme limits lies the most interesting dynamic regime, where the adjustment time of the ocean and of air–sea feedback are comparable to each other. This is the dynamic regime, where ENSO is believed to reside in nature. The coupled modes in this regime have a mixed behavior of free oceanic waves and of the mode that depends primarily on air–sea feedbacks, and can be either stable or unstable depending on the strength of the feedback. These modes can be characterized best by a delayed action oscillator – a prototype model for ENSO. Let T denote sea surface temperature anomaly in the eastern equatorial Pacific, then the time evolution of T obeys a differential delay equation $dT/dt = cT(t) - bT(t - \tau)$, where t is time and τ is a time delay associated with the adjustment of the equatorial ocean. The behavior of T in this model is determined by two competing processes: (1) cT represents the Bjerknes positive feedback, contributing to a growth of sea surface temperature; and (2) $bT(t - \tau)$ represents the delayed oceanic adjustment discussed in the previous section, constituting a negative feedback. This negative feedback due to the oceanic ‘memory’ effect counteracts the positive feedback in the eastern equatorial Pacific with the time delay τ . Physically, this is achieved through excitation of the Rossby waves by off-equatorial wind stress curl and the reflection at the western boundary. Therefore, the time delay τ is essentially determined by the propagation of the Rossby waves from the western central Pacific to the western boundary and of the reflected Kelvin wave from the western boundary to the eastern equatorial Pacific. This negative feedback process is illustrated in Figure 2.

Because both the positive and negative feedbacks are comparable in strength, the differential delay equation can support oscillations with periods longer than the wave adjustment timescale τ . In fact, when realistic parameters are used, the differential delay equation produces an oscillation with a period

Figure 2 Oceanic adjustment associated with the delayed oscillator type of coupled ocean–atmosphere mode. Rossby waves generated by the relaxation of the Trade Winds in the western central equatorial Pacific propagate westward and are reflected into Kelvin waves at the western boundary near the Indonesian archipelago. The Kelvin waves reach the eastern equatorial Pacific with a time delay τ after the relaxation of the Trade Winds and bring cold water to the region, which ultimately shuts down the warm ENSO event. Together with the Bjerknes positive feedback, this negative oceanic feedback process forms the delayed oscillator mechanism for ENSO. Reproduced from Chang, P., Battisti, D.S., 1998. The physics of El Niño. *Physics World* 11, 41–47.

of 3–4 years, which agrees with the average occurrence of El Niño in reality. Therefore, the coupled modes of delayed oscillator type are believed to capture the essential physics of ENSO.

Nonlinear vs Stochastic ENSO Theory

The delayed oscillator theory offers an explanation for the oscillatory behavior of ENSO, but cannot explain the irregularity of ENSO. In nature, an ENSO occurs every 2–7 years with considerable variations in its strength. Where does this irregularity come from? Although answers to this question are not entirely clear, there are two competing theories that offer different views on this issue.

One theory relies on inherent nonlinear interactions within the coupled ocean–atmosphere system. It assumes that the Bjerknes positive feedback is strong enough for the coupled system to reside in an unstable dynamic regime and maintain a self-sustained oscillation at an interannual timescale. This self-sustained oscillation interacts nonlinearly with the annual cycle, which is driven by the seasonal variation of the solar radiation. Because the intrinsic mode of the coupled system oscillates at a different frequency from the driving frequency, nonlinear interaction between the two cycles can give rise to complicated behavior of the coupled system response. Depending upon the relative strength of the driving cycle (the annual cycle) and the intrinsic cycle (the ENSO cycle), the response can be either locked into a periodic cycle (with a period equal to a rational number between the period of annual cycle and that of intrinsic coupled mode; this phenomenon is known as frequency locking in nonlinear dynamics) or chaotic. It is hypothesized that the reality resides in the chaotic regime, and thus the irregularity of ENSO can be attributed partially to the chaos generated by the nonlinear interaction between the annual cycle and the intrinsic oscillating mode of the coupled system.

The other, competing theory puts ENSO in a weak feedback regime, so that the coupled system does not support a self-sustained oscillation, but is forced externally by ‘weather noise’. Here, ‘weather noise’ refers to the high frequency variability that is not generated directly by ocean–atmosphere interactions, but is produced by hydrodynamical instability processes of the atmosphere. Although these high frequency fluctuations of the atmosphere have coherent spatial structure, in time they can be represented approximately as a normally distributed white

noise process. Under these approximations, ENSO can be modeled as a multivariate linear stochastic system, i.e., $(d/dt)s = As + F\xi$, where s is a state vector comprised of sea surface temperature anomalies throughout the tropical Pacific basin; A , a system matrix governing the deterministic dynamics of ENSO; and F represents the spatial distribution of the weather noise whose temporal fluctuations ξ are represented as a normally distributed white noise processes. The sea surface temperature evolution is then determined by the properties of the system matrix A and the noise forcing structure matrix F . In particular, the leading eigenvectors of A give the dominant coupled modes in ENSO system, including the delayed oscillator type of modes. However, since the system is linear, all eigenvectors must be stable, i.e., decaying with time (otherwise the variance would not be bounded). Therefore, they cannot support a self-sustained oscillation and the variability of the system must be maintained by the noise forcing. One important distinction between this view of ENSO physics and the nonlinear theory is that the evolution of ENSO is not necessarily dominated by a single mode (the most unstable mode, according to the nonlinear theory), but rather determined by the interference among many stable modes. Constructive interferences cause sea surface temperature anomalies to grow, whereas destructive interferences cause them to decay. In this theory the irregularity of the ENSO cycle comes naturally because the variability of the system is maintained by a random forcing.

Understanding the cause of ENSO irregularity has important implications for the predictability of this phenomenon. If ENSO evolution is governed by a low-order chaos, then its predictability limit is determined by the inherent nonlinear dynamics of the coupled system. On the other hand, if stochastic processes in the atmosphere are the main cause of ENSO irregularity then its predictability depends not only on deterministic dynamics in the coupled system but also the nature of noise forcing, which is determined largely by the internal dynamics of the atmosphere. These remain topics of active research.

Synopsis

Horizontal structures and dispersion relations of observed equatorial waves are analogous to solutions of the shallow water equations on an equatorial β -plane. In the past few decades, the significance of equatorial waves for tropical meteorology has become increasingly apparent. Equatorial waves exist in the atmosphere and ocean and cause perturbations in dynamical and thermodynamical variables large enough to be crucial for many aspects of tropical weather and climate variability. They form the basic building blocks of tropical circulations. Some aspects of their dynamics remain poorly understood.

Introduction

Equatorial waves serve as the fundamental building blocks of many aspects of tropical weather and climate. They are geophysical fluid waves, existing for a range of spatial and temporal scales, which are trapped near the Equator. They propagate in the zonal and vertical directions, and may exist at any altitude level in the atmosphere or depth in the ocean. They cause oscillations in the pressure, temperature, and winds or currents, with the magnitude of such oscillations being large enough to cause changes in the weather. Conversely, equatorial waves may be excited by energetic weather events, such as by the latent heating of the atmosphere by organized tropical convection. Because equatorial waves transmit energy in the longitudinal and vertical directions, they are a means by which a location in the tropical atmosphere (or ocean) may be influenced by a remote energetic disturbance. This influence can sometimes extend around the entire circumference of the Earth at the Equator.

Like many meteorologically important phenomena, equatorial waves owe their existence to the restoring forces of gravity, the pressure gradient force, and the apparent Coriolis force that applies to displacements of parcels of air or water. The change in sign of the Coriolis force at the Equator allows these waves to take on a discrete set of meridional patterns and causes their trapping near the Equator. Thus, although the Coriolis force is small near the Equator, and consequently geostrophic balance is no longer expected, the rotation of the planet still plays an essential role for these waves.

This article concentrates on equatorial waves that occur in the troposphere, that is, those that most readily influence the weather. The article begins with the theory needed to give a basic understanding of their existence and appearance. In many respects, the theory is equally applicable to equatorial waves existing in the ocean or middle atmosphere. The analysis continues with a simulation of equatorial wave dispersion in a numerical model of the atmosphere. The rest of the article is devoted to observed equatorial waves and their significance for the weather.

Theory

The theory of equatorial waves may start with the (hydrostatic) primitive equations, that is, the full set of basic equations that

govern the time evolution of the three-dimensional large-scale thermodynamic fields in the stratified atmosphere. These equations are often written as six equations in six unknowns: the zonal velocity u , meridional velocity v , vertical velocity w , density ρ , pressure p , and temperature T .

Mathematically, it can be shown that when linearized about a basic state with no (or vertically constant) mean flow, the primitive equations may be reduced, or separated, into the 'shallow water' equations and a vertical structure equation. The shallow water equations govern the horizontal and time-varying behavior of each 'normal mode' of the atmosphere, and are written as three equations in three unknowns only. The vertical structure equation, on the other hand, may be solved to give the vertical structures of each normal mode, as well as the so-called 'equivalent depth' of each of the modes. The equivalent depth also appears in the shallow water equations, and is the depth of the shallow layer of fluid required to give the correct horizontal and time-varying structure of each mode. It provides the link between the vertical structure equation and the shallow water equations, but it also provides an important link between the observed waves and the shallow water theory. Mathematically, the equivalent depth is the separation constant.

This separation of the primitive equations into horizontal and time versus vertical components is very convenient for the derivation of the equatorial waves. As will be shown, the equatorial waves are the solutions, or normal modes, of the equations that are trapped near the Equator.

Horizontal and Time-Varying Structure

The shallow water equations on the rotating Earth in Cartesian geometry may be written as eqns [1]–[3]:

$$\frac{\partial u'_l}{\partial t} - f v'_l = -\frac{\partial \Phi'_l}{\partial x} \quad [1]$$

$$\frac{\partial v'_l}{\partial t} + f u'_l = -\frac{\partial \Phi'_l}{\partial y} \quad [2]$$

$$\frac{\partial \Phi'_l}{\partial t} + g h_l \left(\frac{\partial u'_l}{\partial x} + \frac{\partial v'_l}{\partial y} \right) = 0 \quad [3]$$

where f is the Coriolis parameter ($f \equiv 2\Omega \sin \phi$ where Ω is the angular velocity of the rotation of the Earth and ϕ is the latitude), g is the acceleration due to gravity, h_l is the equivalent

depth, u'_l and v'_l are the (horizontal) velocities in the x and y directions, respectively, and Φ'_l is the geopotential. The primes denote the fact that these are perturbation fields relative to the basic state of no mean flow about which the equations are linearized. The subscript l signifies that these equations govern a particular vertical normal mode only. In the shallow water equations, the unknown variables are a function of horizontal position (x, y) and time (t) only.

As written, these equations are valid for perturbations to the free surface of a shallow layer of incompressible, homogeneous density fluid of mean depth h_l (also called the divergent barotropic model). However, these equations are equally valid for internal modes of the stratified atmosphere, as discussed above, provided the correct choice of h_l is made. Then, to obtain the complete four-dimensional (in x, y, t , and z) structure of the internal normal mode, one must multiply the solutions for u'_l, v'_l , and Φ'_l by the particular internal mode's vertical structure function $G_l(z)$, as in eqn [4].

$$u'(x, y, z, t) = u'_l(x, y, t)G_l(z) \quad [4]$$

Returning to eqns [1]–[3], the approximation that the Coriolis parameter, f , is linearly proportional to the latitude is now made. That is, $f = \beta y$, to give what is called the equatorial β -plane. Equations [1]–[3] then become eqns [5]–[7].

$$\frac{\partial u'_l}{\partial t} - \beta y v'_l = -\frac{\partial \Phi'_l}{\partial x} \quad [5]$$

$$\frac{\partial v'_l}{\partial t} + \beta y u'_l = -\frac{\partial \Phi'_l}{\partial y} \quad [6]$$

$$\frac{\partial \Phi'_l}{\partial t} + g h_l \left(\frac{\partial u'_l}{\partial x} + \frac{\partial v'_l}{\partial y} \right) = 0 \quad [7]$$

Now solutions are sought in the form of zonally propagating waves, eqn [8], where k is the zonal wave number and ω is the frequency.

$$(u'_l, v'_l, \Phi'_l) = \Re\{[\hat{u}(y), \hat{v}(y), \hat{\Phi}(y)] \exp[i(kx - \omega t)]\} \quad [8]$$

Substitution of eqn [8] into eqns [5]–[7] then yields a set of ordinary differential equations in y for the meridional structure functions $\hat{u}, \hat{v}, \hat{\Phi}$, eqns [9]–[11].

$$-i\omega \hat{u} - \beta y \hat{v} = -ik \hat{\Phi} \quad [9]$$

$$-i\omega \hat{v} + \beta y \hat{u} = -\frac{d\hat{\Phi}}{dy} \quad [10]$$

$$-i\omega \hat{\Phi} + g h_l \left(ik \hat{u} + \frac{d\hat{v}}{dy} \right) = 0 \quad [11]$$

This set of equations may be arranged to eliminate both $\hat{u}$ and $\hat{\Phi}$, yielding a second-order differential equation in $\hat{v}$ only (eqn [12]).

$$\frac{d^2 \hat{v}}{dy^2} + \left(\frac{\omega^2}{g h_l} - k^2 - \frac{k}{\omega} \beta - \frac{\beta^2 y^2}{g h_l} \right) \hat{v} = 0 \quad [12]$$

Since wave solutions near the Equator are being considered, the boundary condition for this equation that the solutions will decay at large $|y|$ is required. This boundary

condition is also required so that the equatorial β -plane approximation remains valid. It is the case that eqn [12] with the said boundary condition is of the same form as one encountered in physics, called the Schrödinger equation for a simple harmonic oscillator. Decay of solutions away from the Equator is only satisfied when the constant part of the coefficient in parentheses satisfies the relationship in eqn [13].

$$\frac{\sqrt{g h_l}}{\beta} \left(\frac{\omega^2}{g h_l} - k^2 - \frac{k}{\omega} \beta \right) = 2n + 1; \quad n = 0, 1, 2, \dots \quad [13]$$

This equation gives a relation between the frequency, ω , and the longitudinal wave number, k , for some positive integer number n . That is, it defines the (horizontal) dispersion relations of the equatorial waves. Since it is a cubic equation in ω , there are three roots for ω when n and k are specified. As will be discussed later, n corresponds to the number of nodes in the meridional profile of the meridional velocity, and is thus called the meridional mode number. Also of note is the symmetry of eqn [13] such that the quadrant of wave numbers and frequencies defined by $k < 0, \omega < 0$ is identical to that defined by $k > 0, \omega > 0$. Similarly, the quadrant defined by $k > 0, \omega < 0$ is identical to that defined by $k < 0, \omega > 0$. By eqn [8], these quadrants of wave number–frequency space are separately occupied by eastward- or westward-propagating waves.

Solutions to eqn [13] may be investigated by making various approximations. For example, at low frequencies, the term $\omega^2/g h_l$ can be neglected. This gives eqn [14] as an approximation of one of the three roots.

$$\omega_{\text{Rossby}} \approx \frac{-\beta k}{k^2 + (2n + 1)\beta/\sqrt{g h_l}} \quad [14]$$

The wave class corresponding to this root is called the equatorial Rossby waves. They are westward propagating only, as ω is of the opposite sign to k . For $h_l \rightarrow \infty$, this dispersion relation becomes like that for midlatitude Rossby waves.

At high frequencies, the term $-k\beta/\omega$ in eqn [13] can be neglected. This gives eqn [15] as an approximation for the other two roots of eqn [13].

$$\omega_{\text{IG}} \approx \pm \left[(2n + 1)\beta\sqrt{g h_l} + k^2 g h_l \right]^{1/2} \quad [15]$$

The wave classes corresponding to these roots are called the eastward inertio-gravity (EIG) (for the positive root) and westward inertio-gravity (for the negative root) waves, respectively. For large k and small n , the dispersion of these waves approximates that of pure gravity waves.

All the solutions of eqn [13], computed with no approximation, are shown in Figure 1. The wave number and frequency have been nondimensionalized by taking the units of time and length as given in eqn [16].

$$[T] = (1/\beta\sqrt{g h_l})^{1/2} \quad \text{and} \quad [L] = (\sqrt{g h_l}/\beta)^{1/2} \quad [16]$$

This scaling allows the curves to be plotted irrespective of the value of h_l, β , or g . The three classes of waves discussed so far appear in the bottom left, upper right, and upper left portions of the diagram, respectively. Also shown are the dispersion

Figure 1 Dispersion curves for equatorial waves (up to $n = 4$) as a function of the nondimensional frequency, ω^* , and zonal wave number, k^* , where $\omega^* \equiv \omega / (\beta \sqrt{gh_l})^{1/2}$, and $k^* \equiv k (\sqrt{gh_l} / \beta)^{1/2}$. For all but the Kelvin wave, these dispersion curves are solutions of eqn [13]. Eastward-propagating waves (relative to the zero basic state employed) appear on the right-hand side (i.e., for $k^* > 0$), and westward-propagating waves appear on the left (i.e., for $k^* < 0$).

curves of two additional wave types that require special consideration. They are the $n = 0$ solutions of eqn [13], and the Kelvin wave, for which $\hat{v} = 0$ and which is thus not covered by the solutions of eqn [12] or [13].

The $n = 0$ solution can be obtained directly from eqn [13]. The allowed roots are given exactly by eqn [17].

$$\omega_{n=0} = k \sqrt{gh_l} \left[\frac{1}{2} \pm \frac{1}{2} \left(1 + \frac{4\beta}{k^2 \sqrt{gh_l}} \right)^{1/2} \right] \quad [17]$$

The positive root corresponds to an EIG wave, while the negative root corresponds to a westward-propagating wave. This westward wave is generally called the mixed Rossby-gravity wave, as it shares properties of both the Rossby and inertio-gravity waves. It is also sometimes called the Yanai wave. For $|k| \rightarrow 0$, the positive and negative roots coincide to produce a continuous curve, as can be seen in Figure 1.

The Kelvin wave dispersion curve and horizontal structure are obtained from eqns [9]–[11] by setting $\hat{v} = 0$. Combining the equations to eliminate $\hat{\Phi}$, one is able to show that the Kelvin wave dispersion relation is given by $\omega_{\text{Kelvin}} = \sqrt{gh_l} k$, with the meridional structure of u given by $u_{\text{Kelvin}} = \exp(-\beta y^2 / 2 \sqrt{gh_l})$. This wave is often labeled as the $n = -1$ wave, as its dispersion relation can also be obtained by setting $n = -1$ in eqn [13].

For the horizontal structures of the rest of the waves (i.e., for all waves but the Kelvin wave), one must return to eqn [12]. From the study of the similar Schrödinger equation in physics, it is known that the solutions of eqn [12] are given

exactly by eqn [18], where H_n is the Hermite polynomial of the n th order.

$$\hat{v}(y) = \exp(-\beta y^2 / 2 \sqrt{gh_l}) H_n((\beta / gh_l)^{1/2} y) \quad [18]$$

As required, these solutions for $\hat{v}$ decay for large $|y|$. The first few of the Hermite polynomials are as listed in eqn [19].

$$\begin{aligned} H_0 &= 1, & H_1(\varepsilon) &= 2\varepsilon, & H_2(\varepsilon) &= 4\varepsilon^2 - 2, \\ H_3(\varepsilon) &= 8\varepsilon^3 - 12\varepsilon \end{aligned} \quad [19]$$

As already mentioned, the index n corresponds to the number of nodes in $\hat{v}$ in the domain $|y| < \infty$. These solutions for $\hat{v}$, along with the dispersion relations from eqn [13], may be substituted back into eqns [9]–[11] to obtain the solutions for $\hat{u}$ and $\hat{\Phi}$. The corresponding full horizontal structures, nondimensionalized using the same units of length and time as given in eqn [16], are as displayed in Figure 2. Also shown (in Figure 2(h)) is the full horizontal structure of the Kelvin wave which was obtained from eqns [9]–[11] with $\hat{v} = 0$.

Through inspection of Figures 1 and 2, further properties of these waves can be demonstrated. Note that to obtain a dimensioned value from these figures, the variables must be multiplied and divided by the correct combination of time and length scales; for example, $\Phi = \Phi^* \times [L]^2 / [T]^2$, where Φ^* is the plotted nondimensional geopotential. It is also important to note that because eqns [1]–[3] are linear, any linear combination of the waves described by the figures is also a solution to the equations.

Concentrating for the moment on the dispersion curves for the waves (Figure 1), many of their important properties can be discerned by recalling the equations for the zonal phase speed and the zonal component of the group velocity as $c_p^{(x)} \equiv \omega / k$ and $c_g^{(x)} \equiv \partial \omega / \partial k$, respectively. That is, the group velocity is the local slope of the curves, while the phase speed is determined by the position on the diagram relative to the origin. Thus it can be determined that equatorial Rossby waves only propagate to the west, while their energy (as inferred from the group velocity) may propagate to the east or west, depending on their zonal scale. Mixed Rossby-gravity waves, on the other hand, always have westward phase and eastward energy propagation. Kelvin waves are nondispersive waves, with their phase propagating relatively quickly to the east at the same speed as their group velocity. EIG waves, as their name implies, always have phase propagation to the east. Their group propagation is also always to the east. Finally, westward inertio-gravity waves have phase propagation to the west, and their group propagation is also to the west, except for very low zonal wave numbers. Obviously, the inertio-gravity waves propagate much more quickly than the Rossby waves, while the Kelvin wave has a phase speed of intermediate magnitude.

Typical values of the Kelvin wave phase speed, also known as the gravity wave speed, are in the range of $c_l = \sqrt{gh_l} \approx 10 - 50 \text{ m s}^{-1}$ in the troposphere (corresponding to h_l in the range of 10–250 m), and skewed to higher values in the middle atmosphere. For equatorial waves that propagate along the thermocline (i.e., internally in the ocean), appropriate values of c_l are in the range of $0.5 - 3.0 \text{ m s}^{-1}$ (corresponding to h_l in the range of 0.025–1.0 m).

Now attention may be turned to the wave's horizontal structures as presented in Figure 2, with each wave displayed in

Figure 2 Horizontal structures of the equatorial wave solutions to the shallow water equations on an equatorial β -plane (eqns [5]–[7]), for nondimensional zonal wave number $|k^*| = 1$. All scales and fields have been nondimensionalized by taking the units of time and length as $[T] = (1/\beta\sqrt{gh_i})^{1/2}$ and $[L] = (\sqrt{gh_i}/\beta)^{1/2}$, respectively. The Equator runs through the center of each diagram. Hatching is for divergence and shading for convergence, with a 0.6 unit interval between successive levels. Unshaded contours are for geopotential, with a contour interval of 0.5 units. Negative contours are dashed and the zero contour is omitted. The largest wind vectors are as specified in the bottom right corner. (a)–(d) are for the $n=1$ and $n=2$ inertio-gravity waves; (e) and (f) for the $n=0$ waves; (g) for the $n=1$ Rossby wave; (h) for the Kelvin wave; (i) For the $n=2$ Rossby wave; and (j) for the $n=3$ Rossby wave.

Figure 2 (Continued)

a different panel for a nondimensional zonal wave number of $|k^*| = 1$. The horizontal scale of the waves may be determined by computing the unit of length by which the solutions have been scaled, $[L]$. This scale is also known as the equatorial Rossby radius. It determines the meridional scale of the waves, and is a function of the equivalent depth. For the troposphere, with $h_l \approx 10$ –250 m, $[L] \approx 6$ –13 degrees of latitude. For internal modes in the ocean, however, $[L] \approx 1.3$ –3.3 degrees of latitude. Hence, equatorial waves in the ocean are more closely trapped to the Equator than those in the troposphere.

Fundamental differences in the general structures of the waves can also be seen. For the inertio-gravity waves, the signal of their divergence is very strong, while the magnitude of their winds and geopotential are relatively weak. For Rossby waves the opposite is true. That is, Rossby waves are much more rotational in character than the more divergent inertio-gravity waves.

Vertical Structure

As mentioned in the previous section, to obtain the complete structure of each equatorial wave mode, one must multiply the solutions from the shallow water equations (as presented at an instant in time in Figure 2) by the vertical structure function $G_l(z)$, as in eqn [20], where $G_l(z)$ is governed by the vertical structure equation.

$$u'(x, y, z, t) = u'_l(x, y, t)G_l(z) = \Re\{\hat{u}(y)\exp(ikx - \omega t)\} \times G_l(z) \quad [20]$$

In a dry atmosphere of constant buoyancy frequency N , the vertical structure equation may be expressed as eqn [21].

$$\frac{1}{\rho_0} \frac{d}{dz} \left(\rho_0 \frac{dG_l}{dz} \right) + \frac{N^2}{gh_l} G_l = 0 \quad [21]$$

This equation is a consequence of the mathematical separation. Given the basic state density distribution $\rho_0 \propto \exp(-z/H_s)$, where H_s is the scale height, solutions to this equation may be sought of the form in eqn [22].

$$G_l = \exp(z/2H_s) \exp(\pm imz) \quad [22]$$

Substitution of eqn [22] into eqn [21] then yields eqn [23].

$$m \equiv \frac{2\pi}{L_z} = \left(\frac{N^2}{gh_l} - \frac{1}{4H_s^2} \right)^{1/2} \quad [23]$$

In eqn [23], L_z is the vertical wavelength of the l th normal mode, m is the vertical wave number, $N^2 = ((R/H_s)(dT_0/dz + g/C_p))$ is the buoyancy frequency squared, dT_0/dz is an average lapse rate, and R and C_p are the gas constant and specific heat for dry air, respectively. Equation [23] gives a relationship between the vertical wavelength of a normal mode in a constant N atmosphere, and its equivalent depth, h_l .

Equations [22] and [23] reveal that in a constant N atmosphere, vertical normal modes are sinusoidal in z , with corrections for the density variation with height. In a realistic stratification, however, the modes are only quasisinusoidal, with a local wavelength that is small in regions of large N (such as in the stratosphere) and larger in regions of low N (such as in the troposphere). Example values of the local vertical wavelength computed using eqn [23], given h_l , are presented in

Table 1 Vertical structure values for dry waves in constant N atmosphere^a

h_l (m)	$\sqrt{gh_l}$ (m s ⁻¹)	L_z (km)
$H_s = 7.3$ km, $dT_0/dz = -7.0$ km ⁻¹ (Troposphere)		
10	9.9	6.0
20	14.0	8.5
50	22.1	13.4
100	31.3	19.2
200	44.3	27.9
500	70.0	47.5
$H_s = 6.1$ km, $dT_0/dz = +2.5$ km ⁻¹ (Lower stratosphere)		
10	9.9	2.6
20	14.0	3.7
50	22.1	5.8
100	31.3	8.3
200	44.3	11.8
500	70.0	18.9

^aAs calculated from eqn [23].

Table 1, separately for stratifications representative of the troposphere and lower stratosphere.

The information in Table 1 may be used to estimate which vertical modes are excited by a particular forcing of the atmosphere. For example, if the equatorial atmosphere is forced by the latent heating that occurs in conjunction with atmospheric moist convection, and this heating extends up to the upper troposphere (~ 14 km) with greatest magnitude around the mid-troposphere (~ 7 km), then this heating projects most strongly onto the vertical mode with a vertical wavelength of about 28 km. In the troposphere, this corresponds to an equivalent depth of about 200 m. Such a heating, however, also projects onto other vertical modes (but with reduced strength) because it takes more than one sinusoid to reconstruct a half wavelength in the troposphere. Hence, the resulting complete structure must be computed by a summation of the form in eqn [24], where each u'_l is calculated from the shallow water equations with a different h_l .

$$u'(x, y, z, t) = \sum_l u'_l(x, y, t)G_l(z) \quad [24]$$

Combining vertical modes in this way allows for vertical propagation of a wave packet. Then, phase lines of the wave packet may slope in the vertical, perpendicular to the total wave number vector given by $\vec{k} \equiv (k, m)$, where m is defined to be positive for upward phase propagation and negative for downward phase propagation, assuming that the frequency (ω) is defined to be positive. The total phase of the wave is then given by $\varphi = kx + mz - \omega t$.

Finally, it is important to note that the values in Table 1 apply only when there is no interaction between the waves and moist convection. Theoretical and observational studies have shown that the presence of interacting convection tends to slow down the zonal propagation of waves, or effectively reduce the equivalent depth of the most energetic waves that are seen. For many purposes, however, this theory for the dry waves is very useful for interpretation and understanding, especially in regions such as the stratosphere and over cool sea surface temperatures, where moist convection does not occur.

Model Experiment

Many of the theoretical properties of equatorial waves, as derived in the previous section, may be conveniently illustrated by showing results from a numerical model of the global atmosphere. Here a numerical experiment in which the primitive equations are forced by an imposed heating over 2 days is shown. The heating is representative of latent heating from condensation that occurs within a large aggregation of precipitating convective clouds. The heating is switched on slowly over 1 day, and switched off over the course of the next day. In the vertical, the heating extends from near the surface up to a level of about 14 km, peaking in the mid-troposphere. At its peak, the heating forces the model's equation for potential temperature by an amount equivalent to 10 K day^{-1} , corresponding to a peak precipitation rate of about 40 mm day^{-1} . In the horizontal, the heating spreads over 30 degrees of latitude and 40 degrees of longitude, and is centered on the Equator. The model is integrated forward in time from an initial state of rest with a realistic tropical temperature stratification specified globally, i.e., with tropospheric and stratospheric lapse rates like those specified in Table 1.

Figure 3 shows a horizontal cross section of the model experiment at a level in the upper troposphere. Given the symmetric (with respect to the Equator) nature of the forcing, only equatorial modes that are symmetric about the Equator

are forced. In particular, a Kelvin wave packet propagates to the east from the region of forcing, and a packet of (primarily $n = 1$) Rossby waves slowly develops to the west. Both of these packets are comprised of waves with a number of different wave numbers and frequencies. By the fifth day of the model run, the energy of the Rossby wave packet has dispersed such that a new pair of circulation cells have developed not far from the location of the initial forcing. In contrast, the main Kelvin wave packet has shifted, with little dispersion, half way around the globe.

Figure 4 shows a vertical cross section of the experiment. As explained in the previous section, a heating of this vertical extent projects most strongly onto the vertical mode with an equivalent depth of around 200 m. The main Kelvin wave front in the troposphere, with a vertical half wavelength filling the depth of the troposphere, thus propagates to the east at around 40 m s^{-1} ($\approx \sqrt{9.8 \times 200}$). The projection in the vertical, however, is not restricted to this vertical mode. Therefore, the combination of vertical modes allows vertical energy propagation into the stratosphere via vertically propagating waves, as indicated by the tilted contours of temperature there. In addition, for the same horizontal propagation speed, the vertical wavelength in the stratosphere tends to be about half of that in the troposphere, consistent with Table 1. Indeed, the position of the tropopause at around 100 hPa seems to play an important role in the appearance of the waves.

Figure 3 Horizontal cross section of model experiment at a level of 205 hPa (i.e., in the upper troposphere). Vectors show the horizontal winds, and contours show the temperature perturbations. Contour interval is 0.05 K with the zero contour omitted and negative contours dashed. The maximum vector is 3.8 m s^{-1} on day 1, 6.2 m s^{-1} on day 3, and 6.2 m s^{-1} on day 5. The red coloring in the first panel shows the imposed heating. The axes are labeled with latitude and longitude.

Figure 4 Vertical cross section of model experiment at the Equator. Vectors show the zonal-vertical components of the wind, where the vertical component has been scaled by the same amount that the vertical axis has been stretched. The largest vector on day 5 is 8.1 m s^{-1} . Contours show the temperature perturbations with a contour interval of 0.2 K . Negative contours are dashed. The red coloring in the first panel shows the imposed heating at the levels of $0.5, 3.0, 5.5$, and 8.0 K day^{-1} .

Further consistency with the theory is the appearance of a second Kelvin wave front that is located at about 130°W by day 5 and with a vertical wavelength about three times shorter than the main front. Its speed is also about three times slower than that of the main front. In summary, the linear shallow water theory can be used to understand most aspects of what happens in this model of the atmosphere. In the real world, however, with many other processes and events going on at the same time, equatorial waves are not always so easy to identify.

Observations and Current Understanding

Conclusive observations of the existence of equatorial waves in the atmosphere have been made since the mid-1960s. The first observations were those of mixed Rossby-gravity waves and Kelvin waves. The waves were identified through the analysis of wind measurements from balloon soundings by the researchers

Yanai, Maruyama, Wallace, and Kousky. They were found to be propagating vertically into the stratosphere from a tropospheric energy source, much like the Kelvin waves in the model experiment of the previous section. The waves were also found to be important sources of momentum for the equatorial stratosphere, providing some of the necessary alternating zonal wind accelerations of the stratospheric quasi-biennial oscillation.

A more recent example of such balloon sounding observations of equatorial waves is presented in Figure 5. The soundings were taken from the island of Nauru near the Equator in the Western Pacific. The meridional component of the wind shows a prominent oscillation with a period of around 4–5 days. This oscillation can be identified to be that of a mixed Rossby-gravity wave, because these are the only waves that have a period in this range, for the appropriate range of vertical structures, and have strong meridional winds on the Equator.

This particular event of strong mixed Rossby-gravity waves lasted for about 2 weeks, and was restricted in its location to the Western to Central Pacific. Such events do not

Figure 5 Time-height plot of the meridional component of the wind recorded by balloon soundings taken at the island of Nauru (0.5°S , 166.9°E) from 23 November to the end of 5 December 1992. Contour interval is 3 m s^{-1} , with the zero contour omitted. Southerly winds stronger than 3 m s^{-1} are colored red, northerly winds stronger than 3 m s^{-1} are colored green. Blank areas indicate missing data.

occur all the time, and may occur at different longitudes at different times. To get an appreciation of the global occurrence of equatorial waves in space and time, researchers have used the technique of space-time Fourier spectral analysis. Such analysis gives information on the strength (or 'power') of oscillations in winds or other variables at each wave number and frequency. The technique is particularly useful for the analysis of equatorial waves because it can distinguish between oscillations resulting from eastward versus westward propagation.

Figure 6 shows a particular presentation of the power spectral peaks of a 22-year record of a satellite-observed proxy for tropical moist convection. The proxy for convection is the infrared brightness temperature (T_b) as recorded by multiple satellites and combined into a single dataset known by the Cloud Archive User Services (CLAUS). Infrared T_b data are useful as a measure of tropical moist convection because the tops of deep convective clouds emit much less infrared radiation than the comparatively warm sea or land surface. Before computation of the spectra, the T_b data are decomposed into symmetric and antisymmetric components about the Equator to distinguish between the spectral power that may be contributed by either symmetric or antisymmetric equatorial waves (see **Figure 2**). Once the raw power is computed and summed over the latitudes from 15°S to 15°N , it is divided by an estimate of the red noise background power. It is this ratio that is presented by the contours in **Figure 6**. Spectral regions having a ratio greater than 1.1, that is, with power more than 10% above the background, are shaded. Also shown are the theoretical dispersion curves of the equatorial waves, as in **Figure 1**, except scaled for the three equivalent depths of 12, 25, and 50 m. The match between the spectral peaks of the observed dataset and the theoretical dispersion curves is readily apparent. This match indicates that equatorial waves play an important role in shaping the space and time distribution of tropical convection. That is, equatorial waves have some role in determining when and where tropical convective weather will occur.

Figure 6 A presentation of the wave number–frequency spectral peaks of a long record of CLAUS T_b data, separately for the (a) antisymmetric and (b) symmetric components of the T_b with respect to the Equator, using data for latitudes from 15°S to 15°N . To represent the peaks, the contours show a ratio of the actual power with an estimate of the red noise background power. A ratio of greater than 1.1 is a statistically significant spectral peak (95% level). Also shown are the dispersion curves for the equatorial waves for equivalent depths of 12, 25, and 50 m. The (planetary) zonal wave number is the number of wavelengths that fit around the globe at the Equator. Unit of frequency is cycles per day (cpd). Reproduced from Kiladis, G.N., Wheeler, M.C., Haertel, P.T., Straub, K.H., Roundy, P.E., 2009. Convectively coupled equatorial waves. *Review of Geophysics* 47: RG2003, doi:10.1029/2008RG000266.

The phenomena contributing to these spectral peaks have come to be known as the ‘convectively coupled equatorial waves’. They are described as ‘convectively coupled’ because they involve an interaction between tropical convection and the dynamics of equatorial waves. The convection tends to occur where the waves generate deep upward motions in the troposphere, with the resulting moist convection reinforcing

this upward motion through the associated latent heating of condensation and consequent further generation of upward motion. This interaction modifies the wave’s characteristics from those that occur in a dry atmosphere. In particular, the dispersion of convectively coupled equatorial waves corresponds to shallower equivalent depths than what would occur for the most energetic waves in a dry atmosphere. Not all of the

Figure 7 Composite horizontal structure of a convectively coupled Kelvin wave over the Atlantic/Africa region. Each panel represents a snapshot at a particular point in time, with each panel being separated by 1 day. The green box shows the reference region used for the computation, with the composite being computed relative to a minimum in T_b in the green box at a lag of 0 days. Cold/warm color shadings show negative/positive satellite-observed T_b anomalies (see color scale at right in degree Kelvin). Red/blue contours are for positive/negative 850-hPa geopotential height anomalies (contour interval of 1 m with the zero contour omitted) and vectors are 850-hPa wind anomalies (see scale of vector in bottom panel). Blank areas indicate where the signal of the Kelvin wave is not statistically significant (at the 90% level).

equatorial waves appear as ‘convectively coupled’ signals, such as the $n = 1$ EIG wave that shows no spectral peak in the convection (Figure 6). Why some waves appear as convectively coupled signals and others do not is still not fully understood. The exact nature of the interaction between the convection and dynamics that causes the convectively coupled equatorial waves to occur for the select range of equivalent depths is also not fully understood. Besides these questions, the ubiquitous nature of equatorial waves in the tropical atmosphere is now firmly established. Of further note is the existence of the Madden–Julian oscillation (MJO) in the symmetric spectrum of Figure 6, for eastward planetary zonal wave numbers around 1–4 and periods between 30 and 60 days. The MJO is unlike the convectively coupled equatorial waves in that its spectrum extends across wave numbers and frequencies away from the equatorial wave dispersion curves.

One useful application of the spectral results of Figure 6 is that regions of wave number and frequency can be defined for each wave and used for filtering for that wave. Usually, a box is drawn around each of the spectral peaks to define the wave numbers and frequencies that one will filter for. The filtering is performed using inverse Fourier transforms to retain only the variability that may be associated with each wave. For example, a ‘Kelvin wave-filtered’ time series of T_b data at each location this way may be defined.

A more detailed view of observed equatorial waves may be obtained by averaging together observations of many separate events to produce an image of a typical wave event, or ‘composite’. This can be conveniently done by using observations that have been input into a global weather prediction model and output onto a grid as an observed ‘analysis’. A composite can then be made of all of the global atmospheric data that occur during each phase of the wave. An example of such a composite for the convectively coupled Kelvin wave is given in Figure 7. This figure shows the composite structure of lower tropospheric wind and geopotential height anomalies of a Kelvin wave over a sequence of 5 days, together with the typical signal in the convection, as indicated by the T_b . The composite was computed based on the signal of the Kelvin wave-filtered T_b averaged over the area in the green box in Figure 7. Lag day 0 corresponds to the maximum convection (i.e., minimum of T_b) of the Kelvin wave in this box. In the first panel (i.e., 2 days before the maximum in convection in the reference region), suppressed convection associated with the suppressed phase of the Kelvin wave is occurring in the Gulf of Guinea at longitudes of 0–15° E. At the same time, easterly wind anomalies and negative geopotential height anomalies are occurring slightly to the east over the west coast of Equatorial Africa, and westerly anomalies and positive geopotential height anomalies to the west over the Equatorial Atlantic. In the second panel (i.e., 1 day before the peak in convection in the green box), the whole system has moved eastward; suppressed convection has moved over the Congo Basin about a quarter

wavelength and enhanced convection has moved to be situated near the Equator for the longitudes of 15° W–10° E. Maximum convection in the green box occurs the following day (third panel), and once again there has been a shift of the whole pattern of winds and geopotential to the east. In the last two panels, the enhanced convection associated with the Kelvin wave has shifted into the Congo Basin region, with little dispersion, consistent with the nondispersive character of a theoretical equatorial Kelvin wave. These Kelvin wave disturbances are a robust feature of synoptic timescale convective activity over the Guinea coast and Central Africa during spring. More importantly they can potentially be used to forecast rainfall events in Central Africa with several days ahead, by monitoring their initiation and propagation. Elsewhere in the world, equatorial waves have been linked to the development of tropical cyclones and other severe tropical weather.

Synopsis

The Hadley circulation, a prominent circulation feature characterized by rising air near the Equator and sinking air in the subtropics, defines the position of dry subtropical areas and is a fundamental regulator of the earth's energy and momentum budgets. The character of the Hadley circulation, and its related precipitation regimes, exhibits variation and change in response to both climate variability and radiative forcing changes. The strength and position of the Hadley circulation change from year to year paced by El Niño and La Niña events. Over the last few decades of the twentieth century, the Hadley cell has expanded poleward in both hemispheres, with changes in atmospheric composition (including stratospheric ozone depletion and greenhouse gas increases) thought to have contributed to its expansion. This article introduces the basic phenomenology and driving mechanism of the Hadley circulation and discusses its variations under both natural and anthropogenic climate forcings.

Introduction

The 'Hadley circulation,' named after George Hadley, an English Lawyer and amateur meteorologist, is perhaps the earliest attempt to account for the global-scale distribution of winds in the Earth's atmosphere in terms of basic physical processes. Halley in 1685 and Hadley in 1735 both proposed that the 'trade winds' that blow toward the Equator at low latitudes could be understood as the lower branch of an axially symmetric convection cell driven by the temperature difference between the Equator and poles of the Earth. Their ideas were ahead of their time, especially as there was then no prospect of determining winds at upper levels of the atmosphere and thus verifying their hypothesis. When routine upper-air observations became available in the mid-twentieth century, the ideas of Halley and Hadley were essentially confirmed. Today, the term 'Hadley circulation' refers to the zonally averaged meridional overturning motions in the low-latitude troposphere.

Figure 1 provides a schematic view of the traditional global atmospheric circulation dividing the Earth into a set of climate zones, with the trade wind regime confined to the tropics. The trade winds are simply the low-level part of the overturning 'Hadley cells,' with ascent near the Intertropical Convergence Zone (ITCZ), descent in the subtropics and a poleward return flow at upper levels. The Hadley circulation plays a key role in transporting heat, moisture, momentum meridionally and is an indispensable component for understanding the global climate system and its variability. The descending branch of the Hadley circulation sets the position of the dry subtropical regions (in which most of the world's deserts are found) and is bounded on its poleward flank by the extratropical storm tracks, with mean surface westerly flow. The transition from easterly to westerly flow through the subtropics results in anticyclonic wind stress curl, which drives ocean surface convergence and results in large regions of suppressed ocean biological productivity. Thus, the poleward branches of the Hadley circulation set the location of the main land and ocean deserts, the former through reduced moisture supply and the

latter through reduced nutrient supply. The more disturbed midlatitudes are characterized by generally westerly winds, with irregular growing and decaying eddies, the cyclonic and anticyclonic weather systems generated by baroclinic instabilities. When averaged around entire latitude circles, this turbulent midlatitude flow averages to a weak 'Ferrel circulation,' in which warmer air at lower latitudes sinks and colder air at high latitude rises. There is some evidence of a very weak 'polar cell' at high latitudes.

The energy that drives the Hadley circulation comes from the conversion of heat energy to mechanical energy in the tropical atmosphere: the Hadley circulation is a classic example of a thermodynamic 'heat engine.' Such heat engines are ultimately responsible for maintaining all motions in the atmosphere against the dissipative effects of friction. The operation of the atmospheric heat engine is shown in Figure 2, which is a classic thermodynamic diagram in which temperature is plotted against specific entropy. The thermodynamic state of an air parcel – that is, its temperature, pressure, density, and so on – are represented by a point on the thermodynamic diagram, and any change of its thermodynamic state by a curve on the diagram. The area under the process curve is proportional to the heat energy entering an air parcel. The diagram also shows two different lines of constant atmospheric pressure, one near the Earth's surface and one in the tropical upper troposphere. Near the surface, air flows toward the Equator, along the segment marked AB, gaining heat from the surface (in a manner not so differently from the boundary layer inflow into the eye of a hurricane). Near the Equator, it rises almost adiabatically (i.e., with little heat entering or leaving the air) along the segment BC. It then moves poleward along segment CD, largely maintaining its temperature and angular momentum. The overturning cell is closed by a subtropical descent, as denoted by segment DA, during which the air parcel loses entropy by emitting infrared radiation to space. During this cyclic process, more heat is added to the air along AB and BC than is removed along CD and DA, with the net gain of heat being proportional to the

Figure 1 A schematic view of the mean circulation of the troposphere. The arrows on the globe show the winds near the Earth's surface. The cells at the side show the zonal mean circulation cells at various latitudes.

Figure 2 A schematic thermodynamic diagram for the Hadley circulation.

Figure 3 The annual mean meridional stream function. Contour interval is $2 \times 10^{10} \text{ kg s}^{-1}$. Shading shows zonal winds greater than 20 m s^{-1} . Based on an analysis of 44 years of ERA40 reanalysis.

area enclosed by the loop ABCD in the diagram. The excess heat is converted to mechanical energy associated with the circulation of the tropical air.

The condition for such an energy conversion to take place is that heat should on an average be added at higher pressure than it is removed. Equivalently, one can say that air must rise on average when it is warmer, and descend when it is cooler. A circulation with these properties is called a 'thermally direct circulation.' A thermally indirect circulation, in contrast, must be driven by a source of mechanical energy; a refrigerator cycle is an example of such a thermally indirect circulation. In the schematic diagram of Figure 2, the Hadley circulation is thermally direct, and therefore generates mechanical energy. In contrast, the Ferrel circulation of midlatitudes is thermally indirect and consumes mechanical energy.

The observed annual mean meridional circulation is shown in Figure 3. The contours are parallel to the northward and upward winds averaged around latitude circles and in time. The contour values have been scaled to have units of kg s^{-1} . They may be thought of as denoting the mass flux across a line from the edge of the plot to that point. The most striking feature is the strong rising motion near the Equator, and sinking motion at latitudes of about 25° N and 25° S , defining two overturning cells, the 'Hadley cells,' one in each hemisphere. However, the actual winds associated with these circulations are not particularly strong: they barely exceed 5 m s^{-1} . The diagram also reveals that there is a close relationship between the westerly component of the wind, shown by the gray shading, and the meridional flow. The westerly component is much stronger, with values up to 40 m s^{-1} . These maximum winds, which are the so-called 'subtropical jet,' are found in the upper troposphere, just where the circulations associated with the Hadley cells meet those associated with the Ferrel cells. There is also a close relationship between the zonal winds and the temperature fields: they are linked, to a very good approximation by the thermal wind relationship, which can be written as eqn [1], where u and T denote the zonal wind and temperature averaged around latitude circles, respectively; p is pressure, which decreases with height, and is often used as the vertical

coordinate for the governing equations for the atmosphere; and $R = 287 \text{ J kg}^{-1} \text{ K}^{-1}$ is the specific gas constant for dry air.

$$\frac{\partial u}{\partial p} = \frac{R}{f} \frac{\partial T}{\partial y} \quad [1]$$

That is, a strong vertical wind shear is associated with a strong poleward temperature gradient. In the deep tropics where the Coriolis parameter f is small, this relationship indicates that the temperature gradients must be small, whatever the wind field is. But in the subtropics and midlatitudes, the increasing westerly wind with height is associated with the fall of temperature toward the poles.

The Held–Hou Model

An elegant model due to Held and Hou (1980) gives considerable insight into the Hadley circulation and the factors that determine its extent. Figure 4 illustrates a two-layer representation of the model. The lower layer is affected by friction at the

Figure 4 The configuration of the Held–Hou model.

Figure 5 Solution of Held-Hou model.

ground, and flow within it is supposed to be generally small. Friction is effectively zero in the upper layer and so at this level rings of air conserve their angular momentum as they move poleward. Assuming that such rings start at the Equator with zero zonal wind relative to the solid Earth, the wind at higher latitudes in the upper layer is given by eqn [2], where Ω is the rotation rate of the Earth, a is the radius of the Earth, and y is the distance from the Equator, proportional to the latitude.

$$u_M = \frac{\Omega}{a} y^2 \quad [2]$$

Equation [2] implies that the zonal wind of an air parcel that conserves angular momentum increases rapidly with latitude as it moves poleward. Using the principle of thermal wind balance in the form of eqn [3], the formula for u_M can be used to predict the variation of temperature with latitude, $T_M(y)$.

$$\frac{\partial u_M}{\partial z} = \frac{ga}{2\Omega y} \frac{\partial T_M}{\partial y} \quad [3]$$

Substituting eqn [2] into eqn [3] and solving for T_M , one can see that the upper layer air temperature in conformity with the constraint of angular momentum conservation is proportional to the fourth power of the latitude. That is, T_M is flat near the equator and drops rapidly at subtropics. This is to be compared with the hypothetical 'radiative equilibrium' temperature distribution $T_E(y)$ of an atmosphere that is not permitted to circulate. Where the actual temperature is less than radiative equilibrium there is net heating, and vice versa. In a steady state, this heating and cooling should exactly balance in the Hadley circulation and this requirement fixes the meridional extent and strength of the Hadley circulation.

Figure 5 illustrates a graphical solution of the Held-Hou model. The actual temperature varies very little with latitude in the tropics but drops rapidly in the subtropics and midlatitudes. The radiative equilibrium temperature is maximum at the Equator. The temperature on the equator is set by requiring

that there be no net heating of air parcels as they circulate, that is, that the area shaded in red must be equal to the areas shaded in blue. The poleward limit of the Hadley circulation is at the latitude where these curves cross for the second time. A formula for the distance of the poleward edge of the Hadley cell from the equator results from this solution:

$$Y_H = a\phi_H = \sqrt{\frac{5gH\Delta T}{3\Omega^2 T_0}}, \quad [4]$$

where ΔT is equator-to-pole temperature difference, T_0 the global mean temperature, and H the vertical extent of the Hadley cell. This formula suggests a value for Y_H of about 2500 km, in good agreement with observations considering the simplicity of the model. Elaborating on the Held-Hou model, vertical motions can be estimated, which are proportional to the heating in the regions of ascent and descent. Although the model predicts a vertical circulation that is weaker than that observed, the model can be modified to incorporate the effect of latent heat release in cumulonimbus clouds, which leads to intensified but narrower ascent and broad regions of descent. The basic physical processes in the model, which predicts that the Hadley circulations are confined to 2500 km or so of the equator, remain relevant.

Seasonal Effects

The annual mean circulation shown in Figure 3 is in fact the average of two quite different circulation regimes that persist around the solstices. Figure 6 shows the circulation for the mean Northern Hemisphere winter and summer seasons. In both cases, there is a single strong thermally direct winter Hadley cell with rising motion in the summer hemisphere and descent in the winter hemisphere, while the strength of the summer cell is very much suppressed. Weaker, thermally

Figure 6 The mean meridional circulation for (a) the December–January–February season and (b) the June–July–August season. Other details are as for Figure 3.

indirect Ferrel cells are seen at middle latitudes in both hemispheres. Looking at the mean circulation for shorter periods reveals that the transition between a circulation like that of Figure 6(a) and one like that of Figure 6(b) is quite abrupt. At most times, there is just a single tropical Hadley cell whose circulation links the two hemispheres: at some point in the spring and autumn, its direction of circulation switches abruptly as the insolation (influx of solar energy) maximum crosses the Equator.

The Held–Hou model can be adapted to the situation where the heating is not symmetric about the Equator. Assume that the maximum radiative equilibrium temperature is no longer at the Equator, but at some latitude ϕ_0 . As well as the latitude of the northern and southern edges of the Hadley cells, the latitude ϕ_C of the streamline that divides circulation into the summer and winter hemispheres, and which is not the same as ϕ_0 , must be determined. The algebra is a little more complicated, but the steps in the argument are just the same as for symmetric Hadley cell described in the previous section.

Figure 7 shows the results. For even small ϕ_0 , the summer cell shrinks drastically and the winter cell intensifies. Almost all the circulation is associated with ascent in the summer hemisphere and with descent in the winter. The strength of the circulation is indicated by the area between the temperature curve and the radiation equilibrium curve. For ϕ_0 of only 5° , the winter cell has intensified by a factor of about 10 compared to the symmetric case, while the summer cell has weakened by

a similar factor. The winter cell is therefore some 100 times as intense as the summer cell. Such a highly nonlinear response to the latitude of the heating maximum means that the annual mean meridional circulation is much more intense than the circulation derived from the annual mean heating. This is a particularly pointed example of the problem of ‘nonlinear averaging,’ which is ubiquitous in the study of climate. This result also reconciles the weak circulations of the Held–Hou model with the stronger observed circulation: we should interpret the annual mean circulation as the average of the two solstitial circulations, not as the response to the annual mean thermal forcing.

The Eddy Mediating Effect on the Hadley Circulation

The structure of the Hadley cell is not entirely determined by the tropical heating; fluctuations in the flow (often termed ‘eddies’) also play a significant role in shaping the intensity and structure of the Hadley circulation. The momentum and heat transport by eddies acts to amplify the subtropical portion of the Hadley cell. Evidence suggests that eddies, rather than the energetic closure, have more direct relevance to the terminus of the Hadley cell. An alternative view of how the width of the Hadley cell is determined is that angular-momentum conservation of the upper tropospheric zonal wind continues poleward until the resulting vertical shears become baroclinically

Figure 7 As Figure 5, but for a situation in which the heating maximum is located away from the Equator. ϕ_0 is the latitude of maximum radiative equilibrium temperature, ϕ_C is the latitude dividing the winter and summer Hadley cells, ϕ_W and ϕ_S designate the limits of the winter and summer Hadley cells, respectively.

unstable (Palmén and Newton, 1969; Held, 2000). If one uses the two-layer model's criterion for instability, the terminus of the Hadley cell occurs at the latitude where

$$\frac{\partial H}{\partial y} = \frac{\beta H_0}{f}, \quad [5]$$

where H is the thickness of the upper layer, indicating the tropospheric mean temperature, H_0 is the mean thickness. From thermal wind balance,

$$g^* \frac{\partial H}{\partial y} = f(u_1 - u_2), \quad [6]$$

with the low layer wind $u_2 \approx 0$, then, in the upper layer the criterion can be expressed as

$$u_1 \approx \beta \frac{g^* H_0}{f^2}, \quad [7]$$

where $g^* \equiv \frac{\rho_2 - \rho_1}{\rho_1} g$ is reduced gravity. Invoking the small angle approximation for algebraic simplicity, the terminus of the Hadley cell can be obtained by equating the baroclinically unstable wind with the angular-momentum conserving wind, that is, $u_1 = u_M$. This leads to alternative formula for the width of the Hadley cell:

$$Y_{BC} = a\phi_{BC} = \left(\frac{a^2 g H_0}{\Omega^2 \Delta_v} \right)^{\frac{1}{4}}, \quad [8]$$

where Δ_v is the fractional change in potential temperature in the vertical, representing the bulk static stability of the air column. Substituting into eqn [8] the parameters typically observed for the Earth's climate would give a Hadley cell width of 2500–3000 km, also in good agreement with the observations.

One could combine the two scaling theories for the Hadley cell width by saying that the Hadley cell stops at the smaller of

Y_{BC} and Y_H . If $Y_{BC} < Y_H$, the flow would become unstable before reaching the axisymmetric limit. If $Y_H < Y_{BC}$, on the other hand, the Hadley cell would terminate before becoming baroclinically unstable. Unfortunately, $Y_H \approx Y_{BC}$ based on the observed parameters, rendering it difficult to discern which mechanism is actually operating in the atmosphere. Evidence from analyzing observational data and data from climate models suggests that the instability-based scaling theory is more relevant to the terminus of the Hadley cell in reality. In addition, scaling relation [8] seems to capture the sensitivity of the Hadley cell width to a range of climate change perturbations. The scaling relation [8] can be easily generalized for interhemispherically asymmetric situations. See the schematic in Figure 8 for details.

Near the subtropical edge of the Hadley cell, the vertical motion is primarily maintained by the eddy momentum drag via the so-called 'eddy-pump' effect, and the edge of the Hadley cell tends to align with the transition point between divergence and convergence of the eddy momentum fluxes. Therefore, a third view interprets the Hadley cell terminus as the latitude poleward of which vertical eddy activity fluxes are sufficiently deep to reach the upper troposphere and begin to propagate meridionally, leading to the eddy momentum flux convergence/divergence. However, this midlatitude-centric view has yet to be verified against observation and more realistic atmospheric general circulation model simulations.

Hadley Circulation under Climate Change

Hadley circulation plays a key role in transporting moisture, momentum, and energy in the tropical atmosphere. It also serves as an important conduit for interhemispheric exchange and tropical–extratropical interaction between the thermally direct circulation and the eddy-driven circulation. Both the

Figure 8 Schematic for a scaling relation that distinguishes between winter and summer Hadley cells. The thin solid line indicates the angular-momentum conserving zonal wind profile (u_M), obtained under the assumption of $u = 0$ at the ITCZ ϕ_i . The red lines represent the baroclinic instability criterion for two-layer model. Their intersections with the zonal wind profiles (thick lines) determine the edges of the Hadley cell. The zonal wind in summer cell deviates more from u_M compared to the zonal wind in winter cell due to the greater damping effect from the midlatitude eddies.

intensity and structure of the Hadley circulation can vary due to natural climate variability as well as external climate forcings. For example, El Niño, a climate event that occurs every few years with an anomalous sea surface temperature (SST) warming in the central and eastern equatorial Pacific, can drive an intensification and contraction of the Hadley cell. In accordance to the Hadley circulation response, the midlatitude westerly jet and storm track also shift equatorward. And vice versa for a La Niña. Climate change forcing agents, including greenhouse gases, ozone, aerosols, all can impact on the Hadley circulation.

Increasing the concentration of greenhouse gases can lead to the expansion of the Hadley cell. Since the majority of Earth's driest and arid regions are located in the areas underneath the descending branches of the Hadley circulation around 30° latitude, the expansion of the Hadley circulation can lead to significant changes in precipitation in the latitudes near the edge of the cells. As the areas around the latitudes of the Hadley cell edge become drier, those inhabiting those regions will see less rainfall than traditionally expected, which could cause major problems with water supplies and livability. The mechanisms for the global warming-induced Hadley cell expansion can be complicated. Studies suggested that the amount of the expansion seems to match the scaling relation [8] and attributed the expansion to the increase of the subtropical atmospheric stratification (i.e., Δ_v) under greenhouse warming of the climate.

In fact, we have just witnessed an expansion of the Hadley cell in both hemispheres during the last few decades of the twentieth century. The Southern Hemispheric expansion has been largely blamed on the depleting trend of the stratospheric ozone over Antarctica since the late 1970s. The stratospheric 'ozone hole' in the austral spring to summer not only shifts the jet stream and the storm tracks but also causes the austral summer Hadley cell to expand. These circulation changes result in decrease of precipitation around 45° S and increase of

precipitation around 60° S associated with the poleward-shifted storm track, as well as moistening in the subtropics over the southwestern Indian Ocean, eastern Australia, and southern flank of the Southern Pacific Convergence Zone. The causes for the Northern Hemisphere Hadley cell expansion are more complicated. Aerosols (especially black carbon), tropospheric ozone (as a greenhouse gas), and multidecadal trend of SST might all have contributed to the expansion in the Northern Hemisphere.

Since industrial revolution, the atmosphere has received aerosol pollution more strongly in the Northern Hemisphere more than the Southern Hemisphere, thus imposing an inter-hemispherically asymmetric forcing to the Earth's climate due to the dimming effect of the pollutants. In balancing this radiative perturbation, the 'thermal equator,' where the meridional energy transport of the atmosphere crosses zero, should shift toward the relatively warmed hemisphere since it now does not need as much energy input through transport as it otherwise would. As a consequence, the ITCZ as well as the Hadley cells shifted southward toward the relatively warmed hemisphere. This response, it is believed, has contributed to the devastating drought and famine throughout the Sahel nations in the 1960s–1980s. In fact, any interhemispheric asymmetric forcing for the Earth climate system, including the seasonality in the solar irradiance, orbital forcing, melting of polar ice, oceanic heat flux associated with the Atlantic meridional overturning circulation, etc., can potentially shift the Hadley cell and ITCZ.

A Lagrangian View

The diagrams of the meridional circulation shown so far have all been based on the so-called 'Eulerian averages.' That is, the winds have been averaged at fixed points in space to produce the time-mean, zonal-mean circulation. At all points in space, the winds and temperatures fluctuate to some degree as weather systems pass across the observing site. An alternative is to follow individual elements of fluid as they move around in the atmosphere, and average their properties to define a mean circulation. Such a mean is called the 'Lagrangian mean,' and in many ways is a much preferable way to describe the circulation. For example, the laws of physics applied to the atmosphere all refer to the properties of discrete, identifiable lumps of fluid. However, the Lagrangian mean is very difficult to calculate in practice, not least because individual elements of fluid rapidly become distorted and eventually thoroughly mixed with neighboring elements.

An approximation to the Lagrangian meridional mean circulation can easily be calculated, and is shown in Figure 8. In constructing this diagram, the wind data were averaged not on surfaces of constant pressure (as in Figures 3 and 6) but on surfaces of constant 'potential temperature.' The potential temperature of an air parcel generally remains more or less constant for periods of less than a few days. It follows that surfaces of constant potential temperature move up and down in response to the movement of the air. Averaging on potential temperature surfaces is equivalent, to the degree that potential temperature is indeed conserved, to taking the Lagrangian average.

Figure 9 The mean meridional circulation for December–January–February (DJF), March–April–May season (MAM), June–July–August (JJA), and September–October–November (SON), but with the data zonally averaged on surfaces of constant potential temperature rather than on surfaces of constant pressure. Gray lines show median surface potential temperature. Contour interval is $2.5 \times 10^{10} \text{ kg s}^{-1}$. Computed from ERA40 reanalysis. Adapted from Walker, C., Schneider, T., 2006. Eddy influence on Hadley circulation: simulations with an idealized GCM. *Journal of Atmospheric Sciences* 63, 3333–3350.

Figure 9 differs dramatically from the corresponding Eulerian mean circulation shown in Figure 6. The tropical Hadley cell is still present, but the midlatitude, thermally indirect Ferrel is largely eradicated. Instead, a thermally direct circulation extends all the way from the tropics to the pole in the winter hemisphere. The original picture of the global circulation suggested by Halley and Hadley is largely vindicated if one views the circulation in Lagrangian terms.

The thermally indirect Ferrel cell actually transports heat against the temperature gradient, from high latitudes to low latitudes. At the same time, eddies more than compensate by transporting heat down the temperature gradient, from low latitudes to high latitudes. In fact, the partitioning of the flow into mean and eddy parts is arbitrary. The Lagrangian circulation, dominated by thermally direct circulations at nearly all latitudes, is a more natural and less arbitrary description. However, the Eulerian depiction of the Hadley circulation remains relevant and a useful framework to interpret some of its dynamical impacts on climate.

Synopsis

The Intertropical Convergence Zone (ITCZ) lies in the equatorial trough, a permanent low-pressure feature where surface trade winds, laden with heat and moisture, converge to form a zone of increased convection, cloudiness, and precipitation. The latent heat released in the ITCZ is critical to the atmospheric energy budget and ITCZ cloudiness provides an important contribution to the planetary albedo. The ITCZ's position, structure, and migration influence ocean–atmosphere and land–atmosphere interactions on a local scale, the circulation of the tropical oceans on a basin scale, and a number of features of the Earth's climate on a global scale.

Introduction

One of the features that is most readily identified with the tropical atmosphere is the Intertropical Convergence Zone (ITCZ). The ITCZ lies in the equatorial trough, a permanent low-pressure feature that marks the meteorological equator where surface trade winds, laden with heat and moisture from surface evaporation and sensible heating, converge to form a zone of increased mean convection, cloudiness, and precipitation. The latent heat released in the convective cloud systems of the ITCZ is a critical component of the atmospheric energy balance, and the enhanced cloudiness associated with these cloud systems provides an important contribution to the planetary albedo. The fluxes of heat, moisture, momentum, and radiation between the atmosphere and the surface differ dramatically between the ITCZ region and the regions to the north and south of the ITCZ. Thus, the position, structure, and migration of the ITCZ play an important role in determining the characteristics of ocean–atmosphere and land–atmosphere interactions on a local scale, the circulation of the tropical oceans on a basin scale, and a number of features of the Earth's climate on a global scale.

Mean Structure

On any given day in the tropics, there are usually a number of deep convective cloud systems that appear to be somewhat randomly distributed across the equatorial region. **Figure 1(a)** shows a satellite cloud image constructed from a number of geostationary and polar orbiting satellites for 7 September 1991. Bright areas denote cold temperatures and thus in this case indicate clouds whose tops are at or near the level of the tropopause, e.g., deep convective or cirrus clouds. Dark areas denote warm temperatures, which in this case implies clear skies. Evident throughout the tropical region, and aligned roughly parallel to the equator, are a number of cloud systems. Some of these systems exhibit horizontal scales on the order of a few hundred kilometers or less. Others, such as the large system in the Indian Ocean, have horizontal dimensions on the order of about 25 000 km. The vast difference in horizontal scales of these cloud systems can arise from a number of factors. Typically, the more mature a convective system is, the

larger its horizontal extent. This is mostly due to the development of high cirrus clouds in the outflow region of convective systems. In contrast to deep convective 'towers,' which typically have horizontal scales on the order of 1–10 km and when found in isolation usually indicate young or developing convective system, cirrus clouds can appear to extend over thousands of kilometers and encompass tens or hundreds of convective towers simultaneously. Thus, the size of the various convective systems shown in **Figure 1(a)** can be influenced by their maturity and their abundance in any one area and how these factors in turn influence the development of what appears as a common cirrus cloud. Furthermore, while most cloud systems in the tropics arise from simple convective instability, likely in conjunction with synoptic wavelike disturbances inherent to the equatorial region, the organization of some systems can be influenced by low-frequency phenomena which can increase their spatial extent. For example, the larger systems in the Indian and western Pacific Ocean may be influenced by the tropical Intraseasonal Oscillation or simply be larger due to the difference in climatological conditions (e.g., SST) between the Eastern and Western Hemispheres which is discussed below.

Other than the loose east–west orientation of the cloud systems in **Figure 1(a)**, there is no obvious systematic preference for the locations of these systems. Only upon averaging such observations over a time period relatively long (~months) compared to the lifetime of these systems (~hours–days) does a robust spatial preference become evident. **Figure 1(b)** shows a time-averaged satellite cloud image, constructed from daily cloud images, such as the one shown in **Figure 1(a)**, from 1 September to 31 November 1991. From this image, it is more apparent that for a given season particular regions of the tropics are favored for the development of tropical convective systems. The spatial structure of the deep convective cloud pattern shown in **Figure 1(b)** exhibits the spatial pattern roughly identified with the ITCZ, at least for the Northern Hemisphere fall season. Thus, while the cloud (or rainfall) pattern associated with the ITCZ is usually thought of as a continuous band of clouds (or rain), at any given time, this 'band' contains only a few disparate cloud systems. **Figure 2** shows the long-term mean rainfall pattern. The band(s) of high rainfall represent the mean, or archetypal, ITCZ spatial structure. Overall, this structure is roughly aligned

with the equator and it exhibits a significant amount of zonal symmetry relative to the rainfall pattern in the mid-latitudes. Apart from this zonal symmetry, the ITCZ rainfall distribution displays a fair amount of longitudinal variability as well. In the Atlantic and eastern Pacific Oceans, it is made up of very narrow, intense regions of rainfall that tend to lie just north of the equator. Over the South American and African continents, the mean rainfall distribution has a considerably larger latitudinal extent and tends to lie directly over the equator. Over the eastern Indian and western Pacific Oceans, the rainfall distribution is both broad in latitude and intense in magnitude. Two of the more notable zonal asymmetries in the ITCZ are the weak rainfall over the western Indian Ocean and the southeast extension of the ITCZ over the central Pacific Ocean. The latter, referred to as the South Pacific Convergence Zone (SPCZ), leads to an area of intense rainfall on either side of the equator with

a relatively dry region in between. Such a structure is often referred to as a ‘double ITCZ.’

The time-mean spatial structure of the ITCZ described above can be better understood by examining the time-mean sea surface temperature (SST), which is shown in [Figure 3](#). Due to the fact that on average the equatorial region receives the most solar irradiance, this region also tends to have the highest SSTs. While this tendency for very warm SST (i.e., greater than 25 °C) is mostly uniform with longitude, there are some deviations. These deviations are produced by a number of factors, including ocean basin geometry, ocean circulation properties – equatorial dynamics in particular, as well as the coupled interaction with the atmosphere, including the ITCZ itself. The relatively warm water of the equatorial region heats the air in the lower atmosphere making it less dense and buoyant relative to the air aloft. This buoyancy forcing leads to rising motion

over the equatorial region. As the moist near-surface air rises, it cools adiabatically and begins to undergo condensation which releases the latent heat contained in the water vapor and produces rainfall at the surface. This latent heating enhances the buoyancy and associated upward motion of the air even further, which in turn enhances the adiabatic cooling, water vapor condensation, and surface rainfall. This process continues until nearly all the water vapor condenses out of the parcel and/or the parcel is no longer buoyant with respect to its environment. In either case, this usually happens when the parcel reaches the inversion associated with the tropopause, whereupon the air begins to move away from the equator. This divergent upper level air undergoes cooling through radiative

heat loss, causing it to lose buoyancy, and sinks in the subtropical regions.

Figure 4 shows the long-term mean outgoing thermal radiation leaving the top of the atmosphere. The regions of large radiative heat loss lie on the poleward edges of the regions of high rainfall (i.e., **Figure 2**) and extend into the subtropics. Upon reaching the surface, this sinking air is relatively dry but gains moisture again via surface evaporation as it converges toward the equator. **Figures 5 and 6** show the long-term mean surface wind and evaporation fields. The surface wind field shows that over most of the tropical regions surface air tends to converge into the areas of high rainfall. The evaporation field indicates that as this air converges toward these equatorial

regions, it gains moisture from the ocean, particularly in the areas of the 'trade winds' where the wind speeds are higher. The combination of the above processes leads to a deep meridional circulation cell, extending over the depth of the troposphere, with air converging toward the equator at low levels, rising in the equatorial regions, diverging at upper levels, and sinking in the subtropics. The zonal mean of this circulation pattern is typically referred to as the 'Hadley Circulation.'

From the physical description above, it is evident that a close association exists between the spatial structure of the warmer SSTs and the rainfall pattern associated with the ITCZ. For example, **Figures 2 and 3** show that the narrow bands of rainfall over the Atlantic and eastern Pacific correspond well to the relatively warm bands of warm water north of the equator in these regions. Similarly, the very broad area of warm water in the Indian and western Pacific Oceans corresponds well to the more widespread area of intense rainfall of the ITCZ in these regions. In addition, the discussion above highlights the complex makeup of the water and energy cycles in the tropics and the role of the ITCZ within these cycles. The schematic diagram in **Figure 7** highlights important aspects of these water and energy cycles and illustrates how the physical processes associated with the ITCZ described above fit together in an idealized latitude-height diagram. The downward arrows at the top of the atmosphere depict the incoming solar energy from the sun and the fact that there is a reduction of solar energy as one moves poleward. As **Figure 1(a)** indicates, at any given time, most of the tropics exhibit clear skies. This allows a large portion of this solar energy to reach the surface and induce a pole-to-equator SST gradient, with the warmest SSTs in the near-equatorial region. The upward arrows at the surface of the ocean depict the ocean to atmosphere energy exchange, which takes place primarily through the transfer of heat and moisture from the ocean to the near-surface air via sensible heat and latent (i.e., evaporative) heat fluxes. As the air rises over the warmest water, a convergent circulation is induced at lower levels with the upper levels exhibiting divergence. The rising air experiences adiabatic cooling which leads to condensation of the moisture and the release of the stored latent heat. The

former falls back to the surface as precipitation, while the latter heats the air, leading to a further enhancement of the vertical motion. Now, the heat that was originally derived from incoming solar energy deposited in the ocean resides in the atmosphere. The upward arrows at the top of the atmosphere denote transfer of this energy back to space via radiative heat loss as the air diverges away from the equator and sinks back to the surface.

Seasonal Variations

Over the course of the annual cycle, seasonal changes occurring in the ITCZ modify the mean structure depicted in **Figure 2**. In general, the entire line-oriented convection band marches north in the Northern Hemisphere spring and summer and south in the Southern Hemisphere spring and summer. The differences in the amplitudes and phases of the ITCZ excursions at different longitudes are dictated in part by the different characteristics of the surface (i.e., land or ocean) and the local atmospheric circulation pattern. The ITCZ over land (e.g., Africa and South America) follows the annual march of the sun, while the migration of the ITCZ over extended ocean regions lags slightly behind by a month or two. This time lag is most apparent in the eastern Pacific and the Atlantic Oceans, where the ITCZ is furthest south in the Northern Hemisphere spring and furthest north in the Northern Hemisphere fall. The origin of this time lag is primarily due to the large thermal inertia of the ocean mixed layer compared to the land surface but also involves complex dynamical interactions that develop between the ocean and atmosphere.

While most of the seasonal changes in the ITCZ are associated with latitudinal migration, there are other significant structural changes. One of the more significant of these is over South America where large spatial differences exist between the 'ITCZs' of the Northern and Southern Hemisphere summers. During the Southern Hemisphere summer, the rainy season encompasses nearly the entire tropical area of the South American continent. This produces a latitudinally and

Figure 7 Schematic depiction of the ITCZ within the context of the water and energy cycles of the tropics. The downward arrows at the top of the atmosphere depict the incoming solar energy from the sun. The upward arrows leaving the surface of the ocean depict the transfer of heat and moisture from the ocean to the near-surface air via sensible heat and latent (i.e., evaporative) heat fluxes. The upward arrows at the top of the atmosphere denote this energy being transferred back to space via radiative heat loss.

longitudinally broad ITCZ. In the Northern Hemisphere summer, the ITCZ overlies the oceanic region north of the continent and has a structure more consistent with its oceanic counterparts to the east and west. Another dramatic seasonal change associated with the ITCZ occurs in the Indian Ocean region during the Asian summer monsoon. As the monsoon circulation develops and intensifies, the convection zone splits, with a very intense area of rainfall occurring over the Indian subcontinent and a weaker rainfall maximum remaining in the equatorial region. A similar intensification of rainfall occurs in the Southern Hemisphere summer over northern Australia; however, in this case, the equatorial component tends to be suppressed. During this same period, the convergence zones over Africa and the Indian Ocean become more continuous due to the reduced coastal ocean upwelling off the east African coast. Other modest seasonal deviations occur in the eastern Pacific during the northern spring, when the ITCZ occasionally separates into two zones of convection straddling the equator. This 'double ITCZ' results from a relaxation of the southeast trade winds, which greatly diminishes the equatorial and nearby coastal ocean upwelling leaving seasonably warm surface temperatures south of the equator. In a related manner, the two branches of convergence in the central Pacific oscillate in strength during the year with the southern and northern branches intensifying during their respective summer season.

To help illustrate and quantify some of the seasonal changes in the ITCZ described above, **Figure 8** shows time-latitude diagrams of rainfall over the course of the calendar year for a number of distinct tropical regimes. For example, **Figure 8(a)** shows that the annual cycle of the ITCZ over Africa exhibits a migration pattern that has a nearly sinusoidal nature. In this region, the ITCZ appears to closely follow the solar cycle of surface heating, with a lag of about a month. It has a fairly even intensity throughout the year ($\sim 5 \text{ mm day}^{-1}$) and migrates from about 15° S to 10° N . The difference in poleward extremes is associated with the Sahara Desert, the dryness of which inhibits the northern migration of the ITCZ. In contrast to this nearly sinusoidal case, all other regions (**Figure 8(b)** and **8(g)**) show an annual cycle that has seasonal dependencies in intensity, structure, and/or a larger phase lag relative to the solar cycle of surface heating. For example, the ITCZ migrations over the Indian (**Figure 8(b)**) and western Pacific (**Figure 8(c)**) Oceans show strong rainfall intensification associated with the summer monsoons. In particular, the Asian summer monsoon produces a significant enhancement to the rainfall in the Northern Hemisphere summer months over Southeast Asia and, as mentioned above, produces two bands of rainfall in the Indian Ocean region during this period. The annual cycle of the ITCZ in these two regions lags approximately 2 months behind the solar heating cycle.

The eastern Pacific (**Figure 8(e)**) and Atlantic (**Figure 8(g)**) Oceans have very similar annual cycles. As suggested earlier by **Figure 1(b)** and **Figure 2**, the ITCZ in these regions remains primarily in the Northern Hemisphere throughout the year, with some weak rainfall ($\sim 4\text{--}5 \text{ mm day}^{-1}$) occurring south of the equator in the Northern Hemisphere spring. During this time of year, warm water ($\sim 27^\circ \text{ C}$ or greater) occurs on both sides of the equator in this region and the ITCZ, in its southern most position, is split by a zone equatorial ocean upwelling (i.e., cool equatorial SSTs). The phase of the annual cycle in

these regions lags behind the surface solar heating cycle by approximately 2–3 months, and each produces the most intense ITCZ in the Northern Hemisphere fall. During this season, the surface water associated with the equatorial countercurrents is warmest and the low-level trade wind convergence is strongest.

The annual cycle of the central Pacific and South America shows very different characteristics than those described above. As illustrated earlier in **Figure 2**, the ITCZ in the central Pacific is composed of northern and southern convergence zones straddling the equator. While this large-scale 'double' convergence zone remains intact during the course of the annual cycle, the intensity of the summer hemisphere branch tends to dominate. The annual cycle of the ITCZ over South America displays the least amount of symmetry with respect to north–south migration and ITCZ intensity. The surface underlying the ITCZ is largely responsible for this asymmetry as mentioned above. In this region, the phase of the ITCZ is locked to the annual cycle during its northward propagation. However, after having reached the oceanic region north of South America, the convection diminishes slightly, and the cycle appears to lag slightly until the rainy season begins again over the Amazon Basin in November–December. The annual cycle of the global ITCZ has a modest resemblance to a sinusoidal pattern, with the intensity of the zonally averaged mean rainfall being strongest during the Northern Hemisphere summer and fall ($\sim 7 \text{ mm day}^{-1}$) and weakest during the equinoxes ($\sim 5 \text{ mm day}^{-1}$).

Interannual Fluctuations

Apart from the regular seasonal variations, the ITCZ undergoes interannual fluctuations in its position and intensity. **Figure 9** illustrates the range of interannual variability exhibited by the ITCZ over the period 1979–98 for three of the longitude sectors discussed in the previous section. This figure shows time-latitude diagrams of the seasonal anomalies of rainfall from the mean annual cycles presented in **Figure 8**. Note that each is plotted using the same color scale. Immediately evident is the fact that the interannual anomalies in the ITCZ position and intensity are weakest over Africa and strongest for the ITCZ over the central Pacific Ocean. Typical seasonal rainfall anomalies for the ITCZ over Africa are about $\pm 0.5 \text{ mm day}^{-1}$ and range up to about $\pm 1.5 \text{ mm day}^{-1}$ in the more extreme events. Depending on the location and intensity of the mean ITCZ rainfall band, these values represent variations on the order of 10–25% of the mean values. Overall, these anomalies illustrate that this region undergoes relatively weak, low-frequency rainfall variations with the early and late 1980s being relatively wetter than normal and the late 1970s and early 1990s being relatively drier than normal. Within this low-frequency variability are periods where the ITCZ exhibits short-lived variability in its intensity and latitude. For example, during the 1981–82 winter, the ITCZ extended anomalously southward, while in the 1982–83 winter, the rainfall associated with the ITCZ was about 25% stronger than normal. During the fall of 1986 and summer of 1987, the ITCZ extended anomalously northward, bringing rain to the normally dry Sahara Desert. Another notable anomaly in the ITCZ over Africa occurred in

Figure 8 Time-latitude diagrams of the annual cycle of the ITCZ, in terms of rainfall, zonally averaged over eight different longitude sectors. (a) Africa, 10–40° E; (b) Indian, 60–100° E; (c) W. Pacific, 110–150° E; (d) C. Pacific, 160° E–60° W; (e) E. Pacific, 100–140° W; (f) S. America, 45–75° W; (g) Atlantic, 10–40° W; and (h) global, 0–360° E. Mean annual cycles were computed for the period from 1979 to 1996. Source: National Oceanographic and Atmospheric Administration's (NOAA) Climate Prediction Center (CPC) Merged Analysis of Precipitation (CMAP).

the winter of 1991–92 when the ITCZ was particularly weak and did not migrate as far south as normal.

The time-latitude rainfall anomaly diagram for the Indian Ocean region (Figure 9b) shows variability quite different than that exhibited by the ITCZ over Africa. First, the meridional extent of the anomalous excursions is much greater, extending to at least 30°. For the most part, this is simply related to the much broader latitudinal extent of the mean ITCZ pattern in this region (i.e., Figures 2 and 8). Second, the intensity of the fluctuations is slightly greater, ranging up to about $\pm 3 \text{ mm day}^{-1}$. However, given the larger mean rainfall

values for this region, this anomaly range represents deviations from the annual cycle on the order of 25% which is similar to the case for Africa. Third, even with the seasonal smoothing applied to the data, the ITCZ in this region exhibits considerably more variability at shorter time scales than for example the ITCZ over Africa. This shorter term variability is partly attributable to the Intraseasonal Oscillation that has been found to prevail most strongly over the Indian and western Pacific Oceans. Given the distribution of land and people within this sector, the most consequential of the rainfall anomalies occur in the Northern Hemisphere summer, north of about 15° N.

Figure 9 Time-latitude diagrams of the anomalies in rainfall associated with the ITCZ zonally averaged over three different longitude sectors: (a) Africa, 10–40° E; (b) Indian, 60–100° E; and (c) C. Pacific, 160° E–160° W. Departures are computed from the mean annual cycles shown in Figure 8. Source: National Oceanographic and Atmospheric Administration's (NOAA) Climate Prediction Center (CPC) Merged Analysis of Precipitation (CMAP).

From Figure 7, it can be seen that the maximum rainfall associated with the Indian summer monsoon occurs in July. Figure 8(b) illustrates some aspects of the variability associated with the timing and strength of the Asian monsoon as it relates to the ITCZ. For example, in 1980, the rainfall associated with the northward migration of the ITCZ and the development of the summer monsoon was particularly intense, while the 1981 summer monsoon appears to have come slightly earlier than normal. In contrast, the summer monsoons of 1983, 1987, and 1989 are examples of the monsoon-related ITCZ rainfall being

a bit weaker than normal. It is important to emphasize out that even though these anomalies ($\sim 1 \text{ mm day}^{-1}$) only represent about 10% of the total rainfall that typically occurs during the monsoon (Figure 8(b)), they represent very important departures for the people and industries (e.g., agriculture) that are affected by them.

For the case of the central Pacific (Figure 9c), the anomalous ITCZ rainfall is dominated by negative and positive anomalies on or near the equator. Note that these values are significantly larger than the ITCZ rainfall anomalies occurring

in either of the other longitude sectors discussed above (including those longitude sectors not discussed). In this region, the zonally averaged rainfall anomalies range up to at least $\pm 7 \text{ mm day}^{-1}$. In some instances, particularly for the large anomalies right on the equator, these values can exceed 100% of the mean values associated with the annual cycle (Figure 7(d)). These large variations in the position and intensity of the ITCZ in this region are associated with climate phenomena known as the El Niño – Southern Oscillation (ENSO). In warm phases of ENSO (i.e., El Niño), SST in the central and eastern equatorial Pacific Ocean can become anomalously warm by about $1\text{--}3^\circ\text{C}$, while in cold phases (i.e., La Niña), this region becomes anomalously cool by a similar magnitude. This has a dramatic effect on the organization of tropical convection in this region as well as in regions remote to the central Pacific. Evident from Figure 9(c) are the large positive rainfall anomalies associated the strong El Niño of 1982–83, moderate El Niño of 1986–87, and the prolonged and somewhat weaker El Niño(s) of the early 1990s. Typically, these events cause the two convergence zones which are located

slightly away from the equator in the central Pacific to merge into a single zone of convection and rainfall centered on or very near the equator. The large negative equatorial rainfall anomalies are associated with the La Niñas of 1984, 1988–89, and 1995–96. Central Pacific rainfall anomalies associated with La Niña typically cause the relatively dry equatorial zone near the dateline (Figure 2) to become even drier and to extend further west than normal. It is important to point out that these central Pacific ENSO-related ITCZ rainfall anomalies do not occur in isolation. Typically, these anomalies induce anomalies of the opposite sense and a somewhat weaker magnitude in the western Pacific sector and in some cases the Indian Ocean and South American sectors as well. In fact, these ENSO-related rainfall anomalies are so large that they are the only significant departure that appears to occur in the global mean ITCZ (data not shown). Anomalies in the global mean ITCZ rainfall are typically in phase with the anomalies in the central and eastern Pacific Ocean and have magnitudes that range up to about 1 mm day^{-1} . However, with respect to quantifying the size of this climate signal in the context of the ITCZ, it is important to

Figure 10 Long-term mean (2002–10) satellite-derived cloud fraction maps: (a) high clouds; (b) low clouds. point out that accurate measurements of rainfall over the oceanic regions are possible only with satellite retrievals and this is still an area of active research.

Perspectives from New Satellite Observations

Recently launched satellite instruments provide an unprecedented opportunity to characterize the three-dimensional structure of the ITCZ. **Figure 10** depicts the long-term mean distribution of high and low cloud fractions derived from the Moderate Resolution Imaging Spectroradiometer (MODIS) instrument. The pattern of high cloud fractions (**Figure 10(a)**) largely follows the mean rainfall pattern in **Figure 2**, suggesting the development of deep convective clouds within the ITCZ. Meanwhile, low clouds prevail over subtropical regions over the eastern Pacific and Atlantic Oceans as well as in the southern Indian Ocean (**Figure 10(b)**). Maximum low cloud fractions are exhibited over the eastern portions of these ocean

basins, largely due to coastal oceanic upwelling induced by the trade winds and downward motion in the subtropical high region associated downward branch of the Hadley Circulation (**Figure 7**). Meridional asymmetry in cloud fraction about the equator is clearly evident in **Figure 10(c)** and **10(d)**. Maximum deep cloud fractions are found near 6° N in the globally zonal mean profile (**Figure 10(c)**), largely representing the northward displaced ITCZ over the eastern Pacific and Atlantic Oceans. Meanwhile, minimum high cloud fractions are observed over the subtropical latitudes in both hemispheres, where the maxima in low cloud fractions are evident. In addition to the two peaks over the subtropical regions in both hemispheres, there is a third maximum of low cloud fraction found just north of the equator, which captures the low cloud maximum over the eastern Pacific at this latitude belt (see **Figure 10(b)**). Similar features in high and low cloud profiles are found over the eastern Pacific sector (**Figure 10(d)**). High clouds are largely confined within a narrow latitude belt centered at 9° N. Over the broad region on both sides of the

Figure 11 Long-term mean (1998–2008) satellite-derived total atmospheric diabatic heating at (a) 7 km and (b) 2 km. Latitude-vertical profiles of diabatic heating averaged over (c) global longitudes and (d) eastern Pacific longitudes (160° W– 80° W; see red rectangle in (b)). ITCZ, low clouds dominate whereas high clouds are largely suppressed.

Figure 11 displays spatial distribution of long-term mean total atmospheric diabatic heating at 7 and 2 km as well as its height-latitude profiles averaged over the global longitudes and eastern Pacific sectors. These heating fields are derived based on the measurements from microwave imager and precipitation radar aboard the Tropical Rainfall Measurement Mission (TRMM). The heating pattern at 7 km largely mirrors the mean rainfall pattern in **Figure 2**, suggesting the dominance of the condensational latent heating release in the total diabatic heating over these tropical convective regions. In convectively inactive regions, over regions where low clouds dominate (**Figure 10(b)**) in particular, the total diabatic heating at 7 km is characterized by strong net cooling due to the radiative heat loss in the absence of deep clouds. At 2 km, while strong radiative cooling is still evident over these low cloud regions, heating over the convective regions generally exhibits weaker amplitude compared to that at 7 km. A weak heating center is found over the southern Indian Ocean near 10° S at 2 km, in contrast to the maximum heating near the equator and northern Indian Ocean at 7 km.

The deep structure of the convection over the ITCZ regions is further evident in **Figure 11(c)**, which illustrates the globally averaged mean vertical-latitude diabatic heating profiles. A strong heating maximum is observed to the north of the equator centered at 8° N, stretching from lower troposphere to upper level near 10 km. Another relatively weaker heating center is found to the south of equator near 5° S, reflecting the condensational heating release over the SPCZ and ITCZ over the Indian Ocean. The heating amplitude over the southern branch is much weaker than its counterpart in northern

hemisphere, largely due to the inclusion of the cold SST tongue regions over the eastern Pacific and Atlantic Oceans in the global averages. The strong deep heating structure coupled with the ITCZ convection over the eastern Pacific is further displayed in **Figure 11(d)**, with broad cooling regions present on both sides of the heating area. The strong vertically developed heating over the ITCZ is crucial in driving the atmospheric circulation, which in turn plays a central role in the global water and energy cycles as depicted in **Figure 7**.

Intraseasonal Oscillation (Madden–Julian Oscillation)

RA Madden, National Center for Atmospheric Research, Boulder, CO, USA

© Published by Elsevier Ltd.

Synopsis

The Intraseasonal Oscillation (Madden–Julian Oscillation) reflects the west-to-east movement of very large-scale atmospheric circulation cells in the equatorial plane. Locally, associated variables like surface pressure, winds, and convection oscillate with a typical timescale of 45 days. It is associated with much of equatorial weather variations on the intraseasonal timescale.

Introduction

The global trade winds of the Northern and Southern Hemispheres meet near the Equator in the Intertropical Convergence Zone (ITCZ). Here, the surface air rises in large convective storms mostly over preferred regions of South America, Africa, and the Malay Archipelago, and then moves north and south and east and west at upper levels. The circulations in the north and south directions form the Hadley Cells and those in the east and west directions which are centered on the Malay Archipelago form the Walker Cells. The first are named after George Hadley who described the circulation from tropics to midlatitudes in the 1700s. The Walker Cells are named after Sir Gilbert Walker, a British climatologist. Walker wrote in the 1920s and 1930s about an east-to-west oscillation in pressure between the Indian/West Pacific Oceans and the Southeast Pacific Ocean. It was later learned that this pressure oscillation was accompanied by a longitudinal shift in the main region of upward motion in the east–west circulation cells. They were named the Walker Cells. The pressure oscillation that Walker studied has a dominant timescale on the order of 2–7 years and is now called the ‘Southern Oscillation,’ a part of the El Niño–Southern Oscillation (ENSO). However, circulation in the Walker Cells changes on all timescales, and here is described a variation on an intraseasonal timescale.

Figure 1 captures the rudimentary features of the most important intraseasonal modifications of the average Walker Circulation. Each panel represents a snapshot taken in the equatorial plane about 7–15 days apart with time increasing from top to bottom. Note that convective areas indicated by the cartoon clouds and east–west circulation cells indicated by the streamlines move from the Indian to the Pacific Ocean. The clouds represent large areas of convection on the order of a few thousand kilometers across. The converging and diverging eastward- and westward-directed streamlines are meant to depict regions of horizontal convergence and divergence. Maximum convergence or divergence need not be at the null point of the streamlines as shown. In fact, convection is often shifted into the region of the low-level westerlies. All the features shown in **Figure 1** represent anomalies from the time-averaged tropical circulation. As they move eastward, they modify the clouds in the ITCZ on timescales shorter than a season but longer than a couple of weeks. The average period of the phenomenon is near 45 days. As a result, it has been referred to as the 40–50 day, the 30–60 day Oscillation, and the Intraseasonal Oscillation after its typical timescale, and the Madden–Julian Oscillation (MJO) after authors who described it in the 1970s. The space–

time spectrum of Wheeler (see **Tropical Meteorology and Climate: Equatorial Waves**) also points to the very large spatial scale of **Figure 1** and the typical 30–60 day period.

Even though its existence has been known since the 1970s, much about it is not fully understood. Here, known features and hypotheses about the oscillation are presented.

Description of the Oscillation

Figure 1(a) is meant to convey relatively low surface pressure accompanied by a convergence of moist, low-level air in the Indian Ocean which results in building convection. The tropopause height rises above the convection. The tropopause is the top of the lowest layer of the atmosphere called the troposphere. The weather is confined to the troposphere, which, near the Equator is about 18 km thick. To the east, over the Central Pacific, there is relatively high surface pressure, sinking motion, and suppressed convection. At this time, the circulation in the Walker Cell is increasing with its center of rising motion shifted to west of its average position over the Malay Archipelago. The low-pressure anomalies then move and spread eastward. Local anomalies are on the order of -1 hPa (wet region) to $+1$ hPa (dry region). The area of enhanced large-scale convection and the deeper troposphere also moves eastward at about 5 m s^{-1} to a place in the Western Pacific, close to its time average position (**Figure 1(b)**). Precipitation anomalies are, on average, $\pm 3 \text{ mm day}^{-1}$. Eventually (**Figure 1(c)**), rising motions and convection weaken over the colder equatorial waters of the Central and Eastern Pacific, and high pressure, sinking motion, and suppressed convection reside over the Indian Ocean. The tropopause height falls there too.

After the convection weakens and disappears over the Central Pacific, a wavelike disturbance often continues eastward in the upper troposphere at a faster speed ($10\text{--}20 \text{ m s}^{-1}$). It can propagate the full circumference of the Earth. The oscillation is not so easily detected in the lower troposphere from about 90° W eastward to 20° E , but related convection sometimes can be seen over South America and the Atlantic accompanying the upper-level divergence that is indicated in **Figure 1(d)**. At this time, there is relatively suppressed convection over the Indian and Pacific Oceans. Although the oscillation is irregular, it is present about half the time. It tends to be more active during northern winters.

The accompanying large-scale convective region contains many tall clouds which can be readily identified in infrared satellite measurements because of their very cold tops. **Figure 2** shows cold clouds (blues and greens) over the Indian Ocean in early November

Figure 1 A schematic of the approximate structure of the oscillation in the equatorial plane. The situations summarized in each panel are 7–15 days apart with time increasing downward. Cartoon clouds indicate large regions of increased convection. Streamlines show the east–west circulation with low-level convergence into, and upper-level divergence out of, the convective areas. Wavy line at the top represents the tropopause and that at the bottom anonymous sea level pressure. Reproduced from Madden, R.A., Julian, P.R., 1972. Description of global-scale circulation cells in the tropics with a 40–50 day period. *Journal of the Atmospheric Sciences* 29, 1109–1123.

and again in late December of 2009 that move to the Central Pacific in late November and late January 2010, respectively.

Interestingly, satellite data with higher spatial resolution than that of [Figure 2](#) show that within the eastward-moving large-scale cloudy areas are organized convective cloud clusters of only few hundred kilometers across. These smaller scale features actually move westward.

Besides the eastward movement of the large-scale cloudy regions along the Equator shown in [Figures 1 and 2](#), there

sometimes is some poleward movement of alternately cloudy and fair weather. This poleward movement is most marked over India during the summer monsoon there. Another common variation is eastward propagation to about 100° E longitude and then northeastward or southeastward movement. The former is most common in northern summer and the latter in southern summer, reflecting a connection with clouds of the ITCZ which are typically displaced into the summer hemisphere.

Figure 2 Anomalies from a time average of outgoing longwave radiation for the latitude band 10°S–10°N. Blues and greens are regions of cold temperature and high convective clouds. The vertical axis is time increasing downward from 1 October 2009, 00.00 GMT (2009100100) to 30 January 2010, 00.00 GMT. Patterns sloping diagonally from higher left to lower right imply eastward propagation. A Partial Theoretical Model

The large-scale convective area associated with an oscillation produces considerable heat as rising moist air condenses to form cloud droplets. **Figure 3** shows the theoretically expected response to such heating at the Equator. To the east of the heating, winds blow from the east in the lower troposphere

into the heating region with lowest pressure along the Equator, and back to the east in the upper troposphere with highest pressure along the Equator. The response to the west is characterized by rotating eddies on either side of the Equator. They rotate cyclonically (clockwise in the Southern Hemisphere and counterclockwise in the Northern Hemisphere) about low pressure in the lower troposphere, and anticyclonically about

Figure 3 The theoretical response of winds in the lower and upper troposphere (indicated by the black arrows) to heating. The heating zone is indicated by the yellow ellipses and vertical dotted lines. Lowest relative pressure is within the red line in the lower troposphere, and highest relative pressure is within the blue line in the upper troposphere. Determined from equations in Gill, A.E., 1982. *Atmosphere-Ocean Dynamics*. Academic Press, New York.

high pressure in the upper troposphere. In addition, along the Equator, lower tropospheric winds blow from west to east, and upper tropospheric winds from east to west, in and out of the heating region.

The east side response is a Kelvin wave named after Lord Kelvin who studied water waves along a vertical side boundary. In this case, the Equator, where the vertical component of the Earth's rotation vector changes sign, serves as the vertical side boundary. The west side response is Rossby waves whose existence and behavior are due to the latitudinal variation of that same vertical component of the Earth's rotation vector. C-G Rossby was the first to clearly isolate the dynamics of these waves. Converging low tropospheric winds of the Kelvin and Rossby waves rise in the cumulonimbus clouds of the heating region, and diverge in the upper troposphere.

The observed structure of the oscillation, during its passage from the Indian to Pacific Oceans, is similar in many respects to the forced Kelvin-Rossby waves of Figure 3. It may be that convection building in the equatorial Indian Ocean forces the Kelvin-Rossby waves of Figure 3. The entire complex moves eastward, and upon reaching the cold water of the Central Pacific can no longer support the convection. A free Kelvin wave then continues eastward in the upper troposphere. This scenario would not, however, explain the eastward movement of the large-scale convective region, the typical timescale of the oscillation, nor why it organizes into such a large spatial scale. These important characteristics are not yet fully understood.

Effects of the Oscillation

Figure 2 points to the fact that the oscillation affects weather in the equatorial region. It has a wide range of other known effects as well. They are summarized by the Climate Variability and

Predictability (CLIVAR) Research Project, a part of the World Climate Research Program (WCRP) as follows:

1. Many observational studies have shown anomalously strong MJO activity prior to and during the eastward shifts of the Walker Cells that occur every 2–7 years (warm events of ENSO). Their exact role in timings of ENSO variations is under study.
2. The MJO modulates cyclone activity in many regions of the tropics. *Hurricane* (or *Typhoon*) genesis is two to four times more likely over the Indian, West Pacific, Caribbean, and Atlantic Oceans during its wet phase than during its dry phase.
3. The *Australian Monsoon* is the name of the major rainy season of January and February over Northern Australia. The monsoon onset typically occurs from mid- to late December. Onset is less likely to occur during a dry phase of the MJO. After onset, there are regularly occurring bursts (wet or active periods) and breaks (dry periods) in monsoon activity. Along Australia's North Coast, precipitation can vary as much as 6 mm day^{-1} between burst and break. A large portion of this variability is connected with MJOs.
4. The northern summer season *Asian Monsoon* is affected by MJOs. They also influence breaks and bursts here. The vast majority of monsoon lows occur during enhanced MJO precipitation and upper-level divergence.
5. *High latitude weather* is also affected. This is not surprising since the MJO influences large-scale precipitation in the tropics which, in turn, forces much of the higher latitude weather. Extreme precipitation amounts can fall along the West Coast of North America roughly coincident with MJO phase 1C (Figure 1). MJOs may also affect the Arctic Oscillation (AO) and the Southern Annular Mode (SAM). The AO and SAM are manifested by pressure variations with opposite sign between polar and midlatitudes of the Northern and Southern Hemispheres, respectively, that affect weather patterns.

6. Analysis of satellite measured ocean color data shows that the MJO produces systematic variation in *ocean surface chlorophyll*. Changing surface wind associated with the MJO is a contributing mechanism changing vertical entrainment of nutrients and thus the surface chlorophyll.
7. *African rainfall* variability at intraseasonal time scales is still poorly understood. However, an MJO-like signal with a period of 40–45 days can be seen over much of the continent. Depending on location and season, some 30–40% of intraseasonal rainfall variance can be explained by it.
8. *Variations in total column O₃* appear to be affected by the MJO. Resulting O₃ variations of ± 10 Dobson units are mainly evident in the subtropics, and they are as large as ones associated with annual and interannual timescales. Negative O₃ anomalies flank or lie to the west of MJO convection. This is consistent with a higher tropopause there (**Figure 1**), since the tropopause separates O₃-rich stratospheric air from that of the less rich troposphere.
9. There are easily identified variations in the relative angular momentum (RAM) of the atmosphere, which is the globally integrated west-to-east wind, associated with the oscillation. They are on the order of 10% of the total RAM. By virtue of the fact that total angular momentum of the atmosphere–ocean–Earth system remains very nearly constant, corresponding variations are evident in the Earth’s rotation and the length of day. Required momentum exchanges among atmosphere, ocean, and solid Earth take place through surface wind friction and pressure differences across mountains.

Implications

Improved understanding and more realistic simulations of the MJO (including onset and demise) will contribute to better

forecasting in the global tropics and (at times) in the extra-tropics on a multiple week timescale.

Madden–Julian Oscillation: Skeleton and Conceptual Models

Synopsis

The Madden–Julian Oscillation's (MJO's) 'skeleton' is its fundamental features on intraseasonal/planetary scales: (1) slow eastward phase speed of roughly 5 m s^{-1} , (2) peculiar dispersion relation with $d\omega/dk \approx 0$, and (3) horizontal quadrupole vortex structure. The MJO skeleton model is a minimal, nonlinear oscillator model that captures these three features together. The fundamental mechanism involves interactions between moisture, convective activity, and equatorial fluid dynamics. Further details beyond the MJO skeleton are referred to as the MJO's 'muscle' and include refined vertical structure and upscale convective momentum transport from subplanetary-scale convection and waves.

Introduction

The Madden–Julian Oscillation (MJO) is the dominant component of intraseasonal (≈ 30 – 60 days) variability in the tropics. This variability appears not only in the wind, pressure, and temperature fields, but also in water vapor and convection. The structure of the MJO is a planetary-scale ($\approx 10\,000$ – $40\,000 \text{ km}$) circulation cell with regions of enhanced and suppressed convection, and it propagates slowly eastward at a speed of roughly 5 m s^{-1} . The main regions of MJO convective activity are the Indian and western Pacific Oceans, and the MJO interacts with monsoons, tropical cyclones, El Niño–Southern Oscillation, and other tropical phenomena. Nevertheless, while the MJO is mainly a tropical phenomenon, it also interacts with the extratropics and can affect midlatitude predictability.

The fundamental features of the MJO on intraseasonal–planetary scales are referred to here as the MJO's 'skeleton':

1. Slow eastward phase speed of roughly 5 m s^{-1} ,
2. Peculiar dispersion relation with $d\omega/dk \approx 0$, and
3. Horizontal quadrupole vortex structure.

While these are the salient planetary–intraseasonal features of MJO composites, individual MJO events often have additional features, such as westerly wind bursts, and different varieties of convective features within the MJO envelope. Since these additional features add detailed character to each MJO's structure, and since these features often account for additional strength beyond the MJO's skeleton, they are referred to here as the MJO's 'muscle.'

While the MJO is often described as an intraseasonal–planetary scale phenomenon, it actually has a complex multiscale structure. The MJO's region of enhanced convection is composed of a menagerie of smaller-scale convective processes, including synoptic-scale convectively coupled equatorial waves (CCEWs), mesoscale convective systems (MCSs), and tropical cyclones. Hence the MJO is essentially an envelope of subplanetary-scale convective activity and is a multiscale phenomenon. In light of this, multiscale interactions are a key part of the theory for the MJO's skeleton and muscle.

The MJO skeleton model is a minimal dynamical model that captures the MJO's intraseasonal–planetary scale features 1–3 together. The model is a nonlinear oscillator model whose fundamental mechanism involves interactions between moisture, convective activity, and equatorial fluid dynamics. Before presenting the full MJO skeleton model, these main components are described individually.

Dry Equatorial Long-Wave Equations

The equatorial long-wave equations describe equatorial dynamics on planetary spatial scales of $O(10\,000 \text{ km})$ in the zonal x direction and intraseasonal timescales of $O(10 \text{ days})$ or longer. The equations take the form

$$\frac{\partial u'}{\partial t} - \gamma v' + \frac{\partial p'}{\partial x} = 0 \quad [1]$$

$$\gamma u' + \frac{\partial p'}{\partial y} = 0 \quad [2]$$

$$\frac{\partial p'}{\partial z} = \theta' \quad [3]$$

$$\frac{\partial u'}{\partial x} + \frac{\partial v'}{\partial y} + \frac{\partial w'}{\partial z} = 0 \quad [4]$$

$$\frac{\partial \theta'}{\partial t} + w' = 0 \quad [5]$$

Here u' , v' , and w' are the zonal, meridional, and vertical velocity anomalies, respectively; and p' and θ' are the pressure and potential temperature anomalies, respectively. Notice that the $\partial v'/\partial t$ term is small in this long-wave limit, and hence geostrophic balance is satisfied in the meridional y direction but not the zonal x direction. The Coriolis terms $-\gamma v'$ and $\gamma u'$ vanish at the equator ($y = 0$) and are written using the equatorial beta-plane approximation. The eqns [1]–[5] have been nondimensionalized using the standard equatorial reference scales described in Table 1.

The wave solutions of eqns [1]–[5] can be found by expanding in vertical and meridional basis functions. First, each variable is expanded in terms of vertical structure functions such as $u'(x, y, z, t) = \sum_j u'_j(x, y, t) \sqrt{2} \cos(jz)$, etc. This allows the eqns [1]–[5] to be separated into an infinite number of (long-wave) shallow water systems, where each mode j corresponds to a separate independent (long-wave) shallow water system. For the first baroclinic mode, $j = 1$, the system has the form

$$\frac{\partial u'}{\partial t} - \gamma v' - \frac{\partial \theta'}{\partial x} = 0 \quad [6]$$

$$\gamma u' - \frac{\partial \theta'}{\partial y} = 0 \quad [7]$$

$$\frac{\partial \theta'}{\partial t} - \frac{\partial u'}{\partial x} - \frac{\partial v'}{\partial y} = 0 \quad [8]$$

where the subscript $j = 1$ has been dropped from all variables.

Table 1 Constants and reference scales for nondimensionalization

Parameter	Derivation	Value	Description
β		$2.3 \times 10^{-11} \text{ m}^{-1} \text{ s}^{-1}$	Variation of Coriolis parameter with latitude
θ_0		300 K	Potential temperature at surface
g		9.8 m s^{-2}	Gravitational acceleration
H		16 km	Tropopause height
N^2	$(g/\theta_0)d\bar{\theta}/dz$	10^{-4} s^{-2}	Buoyancy frequency squared
c	NH/π	50 m s^{-1}	Velocity scale
L	$\sqrt{c/\beta}$	1500 km	Equatorial length scale
T	L/c	8 h	Equatorial timescale
	$HN^2\theta_0/(\pi g)$	15 K	Potential temperature scale
	H/π	5 km	Vertical length scale
	$H/(\pi T)$	0.2 m s^{-1}	Vertical velocity scale
	c^2	$2500 \text{ m}^2 \text{ s}^{-2}$	Pressure scale

From Stechmann, S.N., Majda, A.J., Khouider, B., 2008. Nonlinear dynamics of hydrostatic internal gravity waves. *Theoretical and Computational Fluid Dynamics* 22, 407–432. DOI [10.1007/s00162-008-0080-7](https://doi.org/10.1007/s00162-008-0080-7).

Next, through meridional expansion, this long-wave shallow water system can be separated into equations for an infinite set of zonally propagating, equatorially trapped waves. This is achieved by expanding the variables u' , v' , θ' in terms of meridional basis functions such as $u'(x, y, t) = \sum_m u'_m(x, t) \phi_m(y)$ etc. Here the appropriate meridional basis functions are the parabolic cylinder functions, the first few of which are $\phi_0(y) = \pi^{-1/4} \exp(-y^2/2)$, $\phi_1(y) = \pi^{-1/4} \sqrt{2}y \exp(-y^2/2)$, and $\phi_2(y) = \pi^{-1/4} 2^{-1/2} (2y^2 - 1) \exp(-y^2/2)$. Notice the $\exp(-y^2/2)$ factor in each of the parabolic cylinder functions, whose rapid decay away from the equator, $y = 0$, corresponds to the terminology ‘equatorially trapped waves.’ Through such a meridional expansion, one can derive the infinite set of equations

$$\frac{\partial K'}{\partial t} + \frac{\partial K'}{\partial x} = 0 \quad [9]$$

$$\frac{\partial R'_1}{\partial t} - \frac{1}{3} \frac{\partial R'_1}{\partial x} = 0 \quad [10]$$

$$\frac{\partial R'_2}{\partial t} - \frac{1}{5} \frac{\partial R'_2}{\partial x} = 0 \quad [11]$$

$$\frac{\partial R'_3}{\partial t} - \frac{1}{7} \frac{\partial R'_3}{\partial x} = 0 \quad [12]$$

⋮

Here K' , R'_1 , R'_2 , R'_3 , ... are the amplitudes of equatorial long-wave Kelvin and Rossby waves, respectively. The variables $u'(x, y, t)$, $v'(x, y, t)$, $\theta'(x, y, t)$ are recovered using the relationships between the primitive variables $u'_m(x, t)$, $v'_m(x, t)$, $\theta'_m(x, t)$ and the wave amplitudes $K'(x, t)$, $R'_m(x, t)$. For instance, $u'_0(x, t) = [K'(x, t) - R'_1(x, t)/2]/\sqrt{2}$, etc. To illustrate this, Figure 1 shows u' , v' , θ' for the two separate cases with either $K'(x) = -\cos(x)$ or $R'_1(x) = \cos(x)$. These illustrations can be thought of as the meridional structures associated with the wave amplitudes $K'(x, t)$ and $R'_1(x, t)$.

The dispersion relations for the waves from eqns [9] to [12] are seen to be $\omega_K(k) = k$, $\omega_{R1}(k) = -k/3$, $\omega_{R2}(k) = -k/5$, etc., which arise from assuming solutions of the form

Figure 1 Horizontal structures of two unforced ‘dry’ equatorial long-waves: (a) Kelvin wave, and (b) the first equatorial Rossby wave, R'_1 . Contours show lower tropospheric pressure with positive (negative) anomalies denoted by solid (dashed) lines. The contour interval is one-fourth the maximum amplitude of the anomaly, and the zero contour is not shown. Anomalies of convergence (divergence) that are greater than two-thirds the maximum amplitude are shaded dark (light) gray. From Majda, A.J., Stechmann, S.N., 2009b. The skeleton of tropical intraseasonal oscillations. *Proceedings of the National Academy of Sciences U.S.A.* 106 (21), 8417.

$K'(x, t) = \exp \{i[kx - \omega_K(k)t]\}$, etc. Hence these waves are nondispersive in this long-wave limit.

Moisture–Convection Interactions on Intraseasonal–Planetary Scales

Besides the fluid dynamical core, the second main component of the MJO skeleton model is moisture–convection interactions. These quantities are represented by the variables q' and a , respectively:

- q' : lower tropospheric moisture anomaly,
- a : amplitude of the convection/wave activity envelope.

It is noteworthy that, for the MJO skeleton model, it is only the amplitude of the convection/wave activity envelope that is needed, not any of the details of the particular convection/waves that make up the envelope, although the specific details can be important for convective momentum transports (CMTs) or other features of the MJO's 'muscle.' Also notice that a , without a prime, is not an anomaly.

A key part of the q -and- a interaction is how the moisture anomalies influence the convection. The premise is that, for convective activity on planetary–intraseasonal scales, it is the *time tendency* of convective activity – not the convective activity itself – that is most directly related to the (lower tropospheric) moisture anomaly. In other words, rather than a functional relationship $a = a(q)$, it is posited that q mainly influences the tendency – i.e., the growth and decay rates – of the convective activity. The simplest equation that embodies this idea is

$$\frac{\partial a}{\partial t} = \Gamma q' a, \quad [13]$$

where Γ is a constant of proportionality: positive low-level moisture anomalies create a tendency to enhance the envelope of convection/wave activity, and negative low-level moisture anomalies create a tendency to decrease the envelope of convection/wave activity.

The basis for eqn [13], and the physics behind it, comes from a combination of observations, modeling, and theory. Generally speaking, it is well known that tropospheric moisture content plays a key role in regulating convection. On planetary–intraseasonal scales specifically, several studies have shown that the lower troposphere tends to moisten during the suppressed convection phase of the MJO, and lower tropospheric moisture leads the MJO's heating anomaly, which suggests the relationship eqn [13]. Furthermore, this relationship is also suggested by simplified models for synoptic-scale convectively coupled waves, which show that the growth rates of the convectively coupled waves depend on the wave's environment, such as the environmental moisture content. In eqn [13], the factor $\Gamma q'$ acts as a growth/decay rate for the convective activity, and the value of Γ has been estimated from these growth rate variations in idealized models of convectively coupled waves. Lastly, amplitude equations such as eqn [13] have been used in other areas of science and engineering, and they can sometimes be derived from the governing equations using systematic asymptotics.

MJO Skeleton Model

By combining the parameterization eqn [13] with the (long-wave-scaled) linearized primitive eqns [1]–[5], the MJO skeleton model is obtained:

$$\frac{\partial u'}{\partial t} - \gamma v' + \frac{\partial p'}{\partial x} = 0 \quad [14]$$

$$\gamma u' + \frac{\partial p'}{\partial y} = 0 \quad [15]$$

$$\frac{\partial p'}{\partial z} = \theta' \quad [16]$$

$$\frac{\partial u'}{\partial x} + \frac{\partial v'}{\partial y} + \frac{\partial w'}{\partial z} = 0 \quad [17]$$

$$\frac{\partial \theta'}{\partial t} + w' = \bar{H}a - s^\theta \quad [18]$$

$$\frac{\partial q'}{\partial t} - \bar{Q}w' = -\bar{H}a + s^q \quad [19]$$

$$\frac{\partial a}{\partial t} = \Gamma q' a. \quad [20]$$

An equation for the lower-tropospheric moisture q' is also included in the system in eqn [19]. The terms $\pm \bar{H}a$ represent a heat source and moisture sink due to convective activity, and s^θ and s^q represent radiative cooling and a moisture source, respectively.

Notice that this model contains a minimal number of parameters: $\bar{Q} = 0.9$, the (nondimensional) mean background vertical moisture gradient; and $\Gamma = 1$, or $\Gamma \approx 0.2 \text{ K}^{-1} \text{ d}^{-1}$ in dimensional units. The source terms s^θ and s^q must also be specified (see below). Also notice that the parameter $\bar{H}$ is actually irrelevant to the dynamics (as can be seen by rescaling a); it is written here for clarity of presentation: dimensionally, it gives $\bar{H}a$ the units of a heating rate while keeping a nondimensional. The dimensional value of $\bar{H}$ was chosen to be 10 K per day so that a typical value of a is ≈ 0.1 , similar to the nondimensional value of u .

The MJO skeleton model, eqns [14]–[20], is a *nonlinear oscillator* model for the MJO skeleton as a neutrally stable wave. In other words, the model includes neither damping nor instability mechanisms. The fundamental mechanism of the oscillation involves interactions between moisture, convection, and circulation. The nonlinear oscillator component can be seen in the terms $\partial q'/\partial t = -\bar{H}a$ and $\partial a/\partial t = \Gamma q' a$. However, there is also the important moisture convergence term, $\bar{Q}w'$, which couples this q -and- a oscillator to the circulation.

To obtain the simplest model for the MJO, truncated vertical and meridional structures are used. The procedure is analogous to the case of the dry equatorial long-wave equations described above, where equations for the dry zonally propagating, equatorially trapped waves $K'(x, t)$, $R'_m(x, t)$ were derived. For the vertical truncation, only the first baroclinic mode is used in the simplest model so that $u'(x, y, z, t) = u'(x, y, t)\sqrt{2}\cos(z)$, etc. The resulting equations are

$$\frac{\partial u'}{\partial t} - \gamma v' - \frac{\partial \theta'}{\partial x} = 0 \quad [21]$$

$$\gamma u' - \frac{\partial \theta'}{\partial y} = 0 \quad [22]$$

$$\frac{\partial \theta'}{\partial t} - \frac{\partial u'}{\partial x} - \frac{\partial v'}{\partial y} = \bar{H}a - s^\theta \quad [23]$$

$$\frac{\partial q'}{\partial t} + \bar{Q}\left(\frac{\partial u'}{\partial x} + \frac{\partial v'}{\partial y}\right) = -\bar{H}a + s^q \quad [24]$$

$$\frac{\partial a}{\partial t} = \Gamma q' a. \quad [25]$$

Next, for the meridional truncation, the variables are expanded in terms of the parabolic cylinder functions $\phi_m(y)$ as described above for the *dry* equatorial long-wave equations. It is also assumed that q and a have simple equatorial meridional structure proportional to $\exp(-y^2/2)$: $a(x, y, t) = [\bar{A}(x) + A'(x, t)]\phi_0(y)$, where $\bar{A}(x)$ is a background state. For the long-wave-scaled equations, such a meridional heating structure is known to couple with only Kelvin waves and the first symmetric equatorial Rossby waves R'_1 , and the resulting meridionally truncated equations can be written as

$$\frac{\partial K'}{\partial t} + \frac{\partial K'}{\partial x} = -\frac{1}{\sqrt{2}}\bar{H}A' \quad [26]$$

$$\frac{\partial R'}{\partial t} - \frac{1}{3}\frac{\partial R'}{\partial x} = -\frac{2\sqrt{2}}{3}\bar{H}A' \quad [27]$$

$$\frac{\partial Q'}{\partial t} + \frac{1}{\sqrt{2}}\bar{Q}\frac{\partial K'}{\partial x} - \frac{1}{6\sqrt{2}}\bar{Q}\frac{\partial R'}{\partial x} = \left(-1 + \frac{1}{6}\bar{Q}\right)\bar{H}A' \quad [28]$$

$$\frac{\partial A'}{\partial t} = \Gamma Q'(\bar{A} + A'), \quad [29]$$

where the subscript 1 has been dropped from R'_1 for brevity. The equations have been written in terms of anomalies from the state of radiative–convective equilibrium, $\bar{H}\bar{A}(x) = S^\theta(x) = S^q(x)$. Two simple cases are a uniform background state with constant $\bar{S}^\theta = 1$ K per day and a spatially varying state $S^\theta(x)$ that represents a warm-pool sea surface temperature distribution. While $S^\theta(x)$ and $S^q(x)$ are treated here as imposed functions, they could be treated as interactive functions of state variables in order to represent radiative feedback or surface-flux feedback.

An important point is that $K'(x, t)$ and $R'(x, t)$ are the amplitudes of the *structures* of Kelvin and Rossby waves, but these amplitudes in eqns [26] and [27] need not always *propagate* like ‘dry’ waves. In the absence of forcing in eqns [9] and [10], the ‘dry’ long-wave Kelvin and equatorial Rossby wave solutions are dispersionless waves that propagate at 50 and 17 m s^{−1}, respectively. However, in the presence of the coupled dynamical forcing A in eqns [26]–[29], the Kelvin and

equatorial Rossby wave *structures* can be coupled to each other and to Q and A ; and these coupled modes/structures can have propagation speeds very different from 50 or 17 m s^{−1}, and they can be dispersive. One such mode has a mixed Kelvin–Rossby wave structure and dispersion characteristics of the MJO and is summarized below.

Energetics

The nonlinear MJO skeleton model has two important energy principles, in the absence of source terms s^θ and s^q . First, the model eqns [21]–[25] conserve a vertically integrated moist static energy:

$$\partial_t(\theta + q) - (1 - \bar{Q})(u_x + v_y) = 0. \quad [30]$$

Second, this model conserves a positive total energy that includes a contribution from the convective activity a :

$$\begin{aligned} \partial_t \left[\frac{1}{2}u^2 + \frac{1}{2}\theta^2 + \frac{1}{2}\frac{\bar{Q}}{1-\bar{Q}}\left(\theta + \frac{q}{\bar{Q}}\right)^2 + \frac{\bar{H}}{\Gamma\bar{Q}}a \right] \\ - \partial_x(u\theta) - \partial_y(v\theta) = 0. \end{aligned} \quad [31]$$

This total energy is a sum of four terms: dry kinetic energy $u^2/2$, dry potential energy $\theta^2/2$, a moist potential energy proportional to $(\theta + \bar{Q}^{-1}q)^2$, and a convective energy $\bar{H}a/(\Gamma\bar{Q})$. Note that the natural requirement on the background moisture gradient, $0 < \bar{Q} < 1$, is needed to guarantee a positive energy.

Linear Theory Results

Now the linear modes of the model are presented. Since the model eqns [26]–[29] involve four dynamically coupled variables, there are four linear modes. The dispersion relation for the linear modes is shown in Figure 2. (Only the two low-frequency, intraseasonal modes are shown. The other two modes are high-frequency modes and are only weakly coupled to the wave activity.) Figure 2 shows that the skeleton model has eastward-propagating waves with phase speeds of roughly 5 m s^{−1} and the peculiar dispersion relation $d\omega/dk \approx 0$, in agreement with the MJO. Moreover, the phase

Figure 2 Linear wave phase speed ω/k (a) and oscillation frequency ω/k (b) as functions of wave number k for the low-frequency modes of eqns [26]–[29]. Filled circles denote results with the standard parameter values. Other markers denote results with one change made to the standard parameter values: $\bar{Q} = 0.8$ (open circles), $\bar{Q} = 0.95$ (crosses), $\Gamma = 0.5$ (squares), and $\Gamma = 2$ (pluses). Horizontal lines in (b) denote oscillation periods of 30, 60, 90, and 120 days. From Majda, A.J., Stechmann, S.N., 2009b. The skeleton of tropical intraseasonal oscillations. *Proceedings of the National Academy of Sciences U.S.A.* 106 (21), 8417.

speed and dispersion relation are robust over a wide range of parameter values, with the oscillation periods spanning the range of 30–60 days, which is the observed range of the MJO's oscillation period. The westward-propagating waves, on the other hand, which are plotted with positive ω and negative k , have frequencies $\omega(k)$ that vary significantly with k ; moreover, their oscillation periods are seasonal, not intraseasonal, for $k = 1$ and 2. This suggests the first piece of an explanation for the observed dominance of eastward-propagating intraseasonal variability: the westward-propagating modes have seasonal oscillation periods, on which timescales other phenomena are expected to dominate over modulations of convective activity.

The features in Figure 2 are fundamental features 1 and 2 of the MJO skeleton that were mentioned in the Introduction section. For a linear wave, these two features arise from the eigenvalues of the linear system. The second important piece from the linear system is the eigenvectors, which determine the structure of the linear waves and fundamental feature 3 from the Introduction section. When trying to match theory and observations, it is important that both the eigenvalues and the eigenvectors – i.e., all three fundamental features 1–3 – are matched together.

The physical structure of the wave number-2 MJO eigenmode is shown in Figure 3 for the standard parameter values. Horizontal quadrupole vortices are prominent, as in observations, and the maximum convective activity is collocated with the maximum in equatorial convergence. The lower tropospheric moisture leads and is in quadrature with the convective activity, which is also roughly the relationship

seen in observations. The pressure contours display the mixed Kelvin–Rossby wave structure of the wave: equatorial high pressure anomalies are collocated with the westerly wind burst as in Kelvin waves, and they are flanked by off-equatorial low pressure anomalies and cyclonic Rossby gyres, in broad agreement with the observational record. Rectification of the vertical structure and some of the phase relationships is likely due to effects of higher vertical modes as part of the MJO's 'muscle.'

The relative contributions of K , R , Q , and A to these linear waves are shown in Figure 4 for wave numbers 1–3. The MJO has significant contributions from both the Kelvin and Rossby components, whereas the westward modes are dominated by the Rossby component. In addition, the larger Q and A amplitudes suggest the second piece of an explanation for eastward-propagating rather than westward-propagating intraseasonal oscillations: the eastward-propagating modes are more strongly coupled to equatorial moist convective processes.

In addition to these illustrations, a formula for the intraseasonal oscillation frequency ω of the MJO skeleton can be obtained by considering the even simpler case of flow above the equator. In this case, v and γ are set to zero, and meridional derivatives are ignored. The result is a linear system of four equations for u' , θ' , q' , a' :

$$\frac{\partial u'}{\partial t} - \frac{\partial \theta'}{\partial x} = 0 \quad [32]$$

$$\frac{\partial \theta'}{\partial t} - \frac{\partial u'}{\partial x} = \overline{H}a' \quad [33]$$

Figure 3 Physical structure of the wave number-2 Madden–Julian Oscillation mode of eqns [26]–[29] for the standard parameter values. Lower tropospheric velocity vectors are shown with contours of lower tropospheric pressure anomalies (a) and lower tropospheric moisture anomalies (b) with positive (negative) anomalies denoted by solid (dashed) lines. The contour interval is one-fourth the maximum amplitude of the anomaly, and the zero contour is not shown. Positive (negative) anomalies of convective activity A that are greater than one-half the maximum amplitude are shaded dark (light) gray. From Majda, A.J., Stechmann, S.N., 2009b. The skeleton of tropical intraseasonal oscillations. *Proceedings of the National Academy of Sciences U.S.A.* 106 (21), 8417.

Figure 4 Contributions of each component K , R , Q , and A to the linear wave eigenvectors of the Madden–Julian Oscillation (a) and the low-frequency westward-propagating mode (b) for the standard parameter values. Results for wave numbers $k = 1, 2$, and 3 are shown in black, gray, and white, respectively. From Majda, A.J., Stechmann, S.N., 2009b. The skeleton of tropical intraseasonal oscillations. *Proceedings of the National Academy of Sciences U.S.A.* 106 (21), 8417.

$$\frac{\partial q'}{\partial t} + \tilde{Q} \frac{\partial u'}{\partial x} = -\bar{H}a' \quad [34]$$

$$\frac{\partial a'}{\partial t} = \Gamma \bar{a}q'. \quad [35]$$

This system can be solved exactly due to the perfect east–west symmetry:

$$2\omega^2 = \Gamma \bar{S}^\theta + k^2 \pm \sqrt{\left(\Gamma \bar{S}^\theta + k^2\right)^2 - 4\Gamma \bar{S}^\theta k^2 (1 - \tilde{Q})} \quad [36]$$

where k is the zonal wave number, and the radiative cooling rate $\bar{S}^\theta$ is described below eqn [29]. For the low-frequency waves, this is approximately equal to

$$\omega \approx \sqrt{\Gamma \bar{S}^\theta (1 - \tilde{Q})}, \quad [37]$$

For the standard parameter values used here, the oscillation period corresponding to eqn [37] is 45 days, in agreement with observations of the MJO. Notice that this formula is independent of the wave number k ; i.e., this model recovers the peculiar dispersion relation $d\omega/dk \approx 0$ from the observational record, and it relates the MJO frequency to the three parameters of the model.

Nonlinear Simulation

Figure 5 shows a numerical solution of the nonlinear eqns [26]–[29] for a warm-pool sea surface temperature. The convective activity is aligned over the warm pool, which is in the center of the domain from $x \approx 10\,000$ – $30\,000$ km. The MJO events have prominent phases of both active and suppressed convection, and each event has its own individual characteristics in terms of strength, lifetime, regional variations, etc. Furthermore, in addition to the prominent eastward-propagating disturbances, there are instances of localized standing oscillations throughout the domain. For instance, to illustrate this, two rectangular boxes are drawn in Figure 5: $x = 11\,000$ – $15\,000$ km, $t = 3400$ – 3470 days; and $x = 15\,000$ – $19\,000$ km, $t = 3440$ – 3530 days. Localized standing oscillations are prominent again, later, in the region $x = 15\,000$ – $19\,000$ km, $t = 3550$ – 3600 days (for comparison, no box added). The western end of the warm pool is a common location of the standing oscillations, which is in broad agreement with the visual appearance of standing oscillations in the Indian Ocean, sometimes at the beginning of an MJO event.

MJO’s ‘Muscle’

While the MJO skeleton model describes the fundamental planetary–intraseasonal features of MJO composites, individual MJO events often have additional features, such as westerly wind bursts, and different varieties of convective features within the MJO envelope. Since these additional features add detailed character to each MJO’s structure, and since these features often account for additional strength beyond the MJO’s skeleton, they are referred to here as the MJO’s ‘muscle.’

One contributor to the MJO’s muscle is CMT due to the convective systems that are embedded within the MJO’s envelope. These systems include various types of MCSs and CCEWs, and their CMT can potentially accelerate or decelerate the winds associated with the MJO skeleton.

To illustrate the CMT due to MCSs and CCEWs, an exactly solvable model is presented for their velocity anomalies (u', w') and momentum fluxes $\overline{u'w'}$ in a two-dimensional x – z setting above the equator. Consider the following exactly solvable model for a CCEW’s velocity (u', w'):

$$w'(x, z, t) = S'_\theta(x, z, t) \quad [38]$$

$$\frac{\partial u'}{\partial x} + \frac{\partial w'}{\partial z} = 0. \quad [39]$$

In this model, called the weak-temperature-gradient approximation, the wave’s vertical velocity w' is exactly in balance with the heating rate S'_θ , which we must specify. The wave’s horizontal velocity u' is then determined from the

Figure 5 Numerical solution of the nonlinear eqns [26]–[29] for a warm-pool sea surface temperature. Contour plots of (a) $\bar{H}'A'(x, t)$ and (b) $Q(x, t)$. Rectangular boxes show regions of standing oscillations: $x = 11\,000$ – $15\,000$ km, $t = 3400$ – 3470 days; and $x = 15\,000$ – $19\,000$ km, $t = 3440$ – 3530 days. From Majda, A.J., Stechmann, S.N., 2011. Nonlinear dynamics and regional variations in the MJO skeleton. *Journal of Atmospheric Sciences* 68, 3053–3071.

incompressibility constraint in eqn [39]. Given this exact solution for u' and w' of the CCEW, its effect on the larger-scale mean flow is determined by

$$\frac{\partial \bar{u}}{\partial t} = -\frac{\partial}{\partial z} \overline{w'u'}, \quad [40]$$

where this is the horizontal spatial average of the horizontal momentum equation, $\partial_x u + \partial_x(u^2) + \partial_z(wu) + \partial_x p = 0$, and where bar and prime notations are used to denote a horizontal spatial average and fluctuation, respectively:

$$\bar{f}(z, t) = \frac{1}{L} \int_0^L f(x, z, t) dx \quad [41]$$

$$f'(x, z, t) = f - \bar{f}, \quad [42]$$

where periodic horizontal boundary conditions are assumed for simplicity. From eqn [40], it is seen that a CCEW will alter the mean flow if and only if $\partial_z \overline{w'u'} \neq 0$. In the context of convective motions where $w' > 0$, this effect on the mean flow is called CMT.

To illustrate CMT in some specific cases, consider a heat source with two phase-lagged vertical modes, $\sin(z)$ and $\sin(2z)$, which represent deep convective heating and congestus/stratiform heating, respectively:

$$S'_\theta = a_* \{ \cos(kx - \omega t) \sqrt{2} \sin(z) + \alpha \cos[k(x + x_0) - \omega t] \sqrt{2} \sin(2z) \}, \quad [43]$$

where k is the horizontal wave number and a_* is the amplitude of the heating. Two key parameters here are α , the relative

strength of the second baroclinic heating, and x_0 , the lag between the heating in the two vertical modes. Heating structures of this form are commonly associated with MCSs and CCEWs, due to variations in congestus, deep, and stratiform cloud populations. Figure 6 shows three cases for the lag x_0 : 0 (top), +500 km (middle), and –500 km (bottom) for a wave with wavelength 3000 km, heating amplitude $a_* = 4$ K per day, and relative stratiform heating of $\alpha = -1/4$. The lag determines the vertical tilt of the heating profile. Given this heating rate, the velocity can be found exactly from eqn [39]:

$$u'(x, z, t) = -\frac{a_*}{k} \{ \sin(kx - \omega t) \sqrt{2} \cos(z) + 2\alpha \sin[k(x + x_0) - \omega t] \sqrt{2} \cos(2z) \} \quad [44]$$

$$w'(x, z, t) = a_* \{ \cos(kx - \omega t) \sqrt{2} \sin(z) + \alpha \cos[k(x + x_0) - \omega t] \sqrt{2} \sin(2z) \} \quad [45]$$

With this form of u' and w' , the eddy flux divergence is

$$\frac{\partial}{\partial z} \overline{w'u'} = \frac{3}{2} \frac{\sin(kx_0)}{k} a_*^2 \alpha [\cos(z) - \cos(3z)] \quad [46]$$

Notice that a wave with first and second baroclinic components generates CMT that affects the first and *third* baroclinic modes. Also notice that eqn [46] is nonzero as long as $\alpha \neq 0$ (i.e., there are both first and second baroclinic mode contributions) and $x_0 \neq 0$ (i.e., there is a phase lag between the first and second baroclinic modes). MCSs and CCEWs in nature typically have this type of structure.

For illustrations of the above exact solutions, consider the three cases shown in Figure 6: upright updraft (top), westward

Figure 6 Solutions to the exactly solvable model eqns [38] and [39] for convectively coupled equatorial waves (CCEWs) structure and convective momentum transport in three cases: upright updraft (top), vertically tilted updraft of ‘eastward propagating’ CCEW (middle), and vertically tilted updraft of ‘westward propagating’ CCEW (bottom). Left: vector plot of (u', w') and shaded convective heating $S'_\theta(x, z)$. For vectors, the maximum u' is 6.0 m s^{-1} for the top and 4.0 m s^{-1} for the middle and bottom, and the maximum w' is 2.8 cm s^{-1} for the top and 2.2 cm s^{-1} for the middle and bottom. Dark shading denotes heating, and light shading denotes cooling, with a contour drawn at one-fourth the maximum and minimum values. Middle: vertical profile of the mean momentum flux $\overline{w'u'}$. Right: negative vertical derivative of the mean momentum flux $-\partial_z \overline{w'u'}$. From Stechmann, S.N., Majda, A.J., Skjorshammer, D., 2013. Convectively coupled wave–environment interactions. *Theoretical and Computational Fluid Dynamics* 27, 513–532. DOI [10.1007/s00162-012-0268-8](https://doi.org/10.1007/s00162-012-0268-8).

propagating’ CCEW (middle), and ‘eastward propagating’ CCEW (bottom). Although there is no inherent definitive propagation in the exactly solvable model eqns [38] and [39], propagation direction labels are assigned to the vertical tilt directions according to the structures of observed CCEW: heating is vertically tilted with leading low-level heating and trailing upper-level heating with respect to the CCEW propagation direction. Specifically, the middle row of Figure 6 corresponds to the observed structures of convectively coupled Kelvin waves, which propagate eastward, and the bottom row of Figure 6 corresponds to westward-propagating inertia-gravity waves (also called ‘two-day waves’). Also shown in

Figure 6 are the average vertical flux of horizontal momentum, $\overline{w'u'}$, and its vertical derivative, $\partial_z \overline{w'u'}$. These exact solutions show that upright updrafts have zero CMT, and tilted updrafts have nonzero CMT with the sign determined by the CCEW’s propagation direction. Note that the vertically averaged momentum would not be affected by CMT in this model, since $\overline{w'u'}$ is necessarily zero at the upper and lower rigid boundaries. Westerly wind bursts, which refer to lower tropospheric winds, can be accelerated by CMT due to eastward-propagating MCSs and CCEWs, as illustrated in the middle row of Figure 6.

One effect that is not included in the model eqns [38] and [39] is the effect of the larger-scale mean wind $\bar{u}(z, t)$ on the

MCSs or CCEWs. This could affect whether eastward- or westward-propagating convective system is favored in a given environment, which, in turn, affects the CMT. Moreover, the larger-scale mean wind $\bar{u}(z, t)$ is also needed, in addition to $\overline{w'u'}$, in order to classify momentum transport as either ‘upscale’ or ‘downscale.’ For example, according to eqn [40], if $-\partial_z \overline{w'u'} > 0$ and $\bar{u}(z, t) > 0$ at some level z , then the large-scale mean wind $\bar{u}(z, t)$ is accelerated, and the momentum transport is ‘upscale’ because the smaller-scale MCSs or CCEWs cause an increase in the large-scale mean wind. Conversely, in the same situation but with $\bar{u}(z, t) < 0$, the large-scale mean wind is decelerated, and the momentum transport is ‘downscale.’

Monsoon: Overview

J Slingo, University of Reading, Reading, UK

This article is reproduced from the previous edition, volume 3, pp 1365–1370, © 2003 Elsevier Ltd.

Monsoon derives from the Arabic word 'mausam', meaning season, and in its broadest definition describes those climates that are seasonally *arid*. As shown in Figure 1, many regions of the tropics and subtropics experience a rainy summer season and a dry winter season, although regions close to the Equator can often experience two rainy seasons; e.g., equatorial east Africa with its 'long' (March–May) and 'short' (October–December) rains. The main driver of this marked seasonality in rainfall is the change in the distribution of surface heating between winter and summer, primarily associated with seasonal variations in the position of the sun. Because of this close relationship with the solar seasonal cycle, the start of the rainy season often begins with remarkable regularity each year.

Although Figure 1 shows that many regions are seasonally arid, the more precise definition of a monsoon climate, as proposed by Ramage, identifies South Asia, Australia, and Africa as having distinct monsoons. Ramage's criteria for a monsoon to exist are as follows:

1. Prevailing wind direction shifts by at least 120° between January and July.
2. Prevailing wind direction persists for at least 40% of the time in January and July.

3. Mean wind exceeds 3 m s^{-1} in either month.
4. Fewer than one cyclone–anticyclone alternation occurs every 2 years in either month in a 5° latitude–longitude rectangle.

These criteria essentially demand that a monsoon be characterized by a wind regime that is steady, sustained and therefore inherently driven by the seasonally evolving boundary conditions, such as land or ocean surface temperatures. It excludes most extratropical regions that are characterized by synoptic weather systems with alternating cyclonic–anticyclonic circulations.

Based on these criteria, Figure 2 shows that this major reversal in the seasonal wind regimes only occurs over (1) India and South-East Asia, (2) northern Australia, and (3) West and central Africa. These three regions constitute the major monsoons of the global circulation. Although the Americas and South Africa also experience a strong seasonal cycle in rainfall, the prevailing wind direction is largely unchanged between winter and summer (Figure 2), and so strictly speaking cannot be classified as monsoon regions. The name 'monsoon' is often used to denote the rainy season, but in fact can relate to both extremes of the seasonal cycle. The term winter monsoon is used in South-East Asia to describe the dry, north-easterly

Figure 1 Mean precipitation distributions for northern winter (January–February; upper panel) and northern summer (July–August; lower panel) at the height of the monsoon season (units: mm day^{-1}). (Data source: Global Precipitation Climatology Project.)

Figure 2 Mean winds at 925 hPa for northern winter (January–February; upper panel) and northern summer (July–August; lower panel) at the height of the monsoon season (units: m s^{-1}). (Data source: Reanalyses from European Centre for Medium Range Weather Forecasts for 1979–93.)

winds that prevail over the northern Indian Ocean and South China Sea during boreal winter (Figure 2, upper panel).

For a monsoon to be established, a thermal contrast between the land and ocean must exist. This occurs when large land masses, such as Asia, Africa, and Australia, heat up rapidly during the spring and summer (Figure 3). Since the thermal inertia of the land is much less than the surrounding oceans, the continents respond much more rapidly to the seasonal cycle in solar heating, setting up large temperature gradients. These hot land masses draw humid air in from the surrounding oceans, like a massive sea breeze (Figure 2). As the moisture-laden air reaches the warm land, it rises, the moisture condenses, and the rainy season begins. By contrast, in winter the land becomes much cooler than the surrounding oceans and cold, dry air then flows from the land out over the ocean. Often the two monsoons, winter and summer, are closely linked with the winter monsoon of one hemisphere feeding the summer monsoon of the other. For example, in the Asian–Australian monsoon system, the dry air from the winter continent flows across the Equator toward the summer hemisphere (Figure 2), picking up moisture from the warm oceans and feeding the monsoon rains over the summer continent.

A critical factor that determines the generation of a monsoon is the geographical orientation of the oceans and continents. The strongest monsoons occur where there is a pronounced north–south distribution in land and ocean that can take advantage of the north–south progression of the solar seasonal cycle. As Figure 3 shows, the largest land–sea temperature contrasts occur over the seasonally arid regions of North Africa, India, and Australia, during the months preceding

the summer monsoon. These very warm temperatures lead to the development of thermal lows which serve to pull in air from surrounding regions. Once the monsoon is established and the rains begin, the land surface temperatures tend to cool due to the increased soil wetness, but the atmospheric warming from latent heat release associated with the monsoon rains (Figure 1) maintains the low-pressure regions (Figure 4) which continue to drive the monsoon winds.

Although this classic description of monsoons provides the fundamental basis for their existence, there are important regional differences associated with the shape of continents, orography (particularly mountain barriers), and ocean temperatures. For the Asian summer monsoon, the Tibetan plateau acts as an elevated heat source which clearly influences the establishment and maintenance of the monsoon circulation. The seasonal heating of the plateau leads to a reversal of the meridional temperature gradient which extends throughout the troposphere (Figure 5). This reversal is instrumental in triggering the large-scale seasonal change in the circulation over East Asia, with the poleward transition of the subtropical jet and the onset of the monsoon over the Indian subcontinent.

The importance of this deep warm core over South Asia is demonstrated in Figure 6, which shows the winds in the free troposphere at 700 hPa. These winds can be compared with the boundary layer winds at 925 hPa in Figure 2. It is only for the domain of the Asian monsoon that the seasonal reversal of the winds is seen extending above the boundary layer into the free troposphere. This is important because it is only when there is advection of moist air through a substantial depth of the troposphere that sustained monsoon rainfall is achieved.

Figure 3 Surface temperatures for early austral summer (November–December; upper panel) and boreal summer (May–June; lower panel) at the onset of the monsoon (units: °C). (Data source: Reanalyses from European Centre for Medium Range Weather Forecasts for 1979–93.)

Figure 4 Mean sea-level pressure for northern winter (January–February; upper panel) and northern summer (July–August; lower panel) at the height of the monsoon season (units: hPa). (Data source: Reanalyses from European Centre for Medium Range Weather Forecasts for 1979–93.)

Figure 5 Mean temperature between 200 and 500 hPa for northern winter (January–February; upper panel) and northern summer (July–August; lower panel) at the height of the monsoon season (units: K). (Data source: Reanalyses from European Centre for Medium Range Weather Forecasts for 1979–93.)

Figure 6 Mean winds at 700 hPa for northern winter (January–February; upper panel) and northern summer (July–August; lower panel) at the height of the monsoon season (units: m s^{-1}). (Data source: Reanalyses from European Centre for Medium Range Weather Forecasts for 1979–93.)

The significance of the Tibetan plateau is further demonstrated when a comparison is made between the summer monsoons of South Asia, northern Australia, and West Africa. In the absence of an orographic heat source, the seasonal reversal of the meridional temperature gradient through the depth of the troposphere is barely evident over Australia and West Africa. This is despite the very substantial surface warming of Australia and North Africa shown in [Figure 3](#). The effect of the confinement of the seasonal reversal in the meridional temperature gradient to the near-surface layers over Africa and Australia can be seen in the winds at 700 hPa ([Figure 6](#)). Unlike South-East Asia, there is no seasonal reversal of the winds in the free troposphere so that a deep moist layer is not established in the same way as over South Asia. Consequently, the monsoon rains of West Africa and Australia are not as intense, nor do they extend as far polewards.

Monsoons are crucial elements of the global circulation and monsoon rainfall provides the water needed by over 60% of the world's population. Understanding and predicting how monsoons may change from year to year, and the result of global warming are key scientific, economic and societal issues. The management of water resources is a top priority for monsoon-affected countries to enable the population to survive from one rainy season to the next. Food production in seasonally arid areas is also inherently risky. By the end of the

dry season, the soil is parched and planting cannot begin until the rains arrive. A late or weak monsoon can lead to a short or poor growing season and hence low yields. Agricultural failure has a profound effect on the economy of monsoon-affected countries, such as India, where farming accounts for 30% of the gross domestic product and 67% of the workforce.

Elements of a Monsoon Circulation

A monsoon is a circulation system with certain well-defined characteristics. During summer, lower tropospheric winds flow toward heated continents away from the colder oceanic regions of the winter hemisphere. In the upper troposphere the flow is reversed, with flow from the summer to the winter hemisphere. Precipitation generally occurs during summer, centered in time on either side of the summer solstice and located over the heated continents and the adjacent oceans and seas in the vicinity of a trough of low pressure referred to as the 'monsoon trough'. Most summer rainfall is associated with synoptic disturbances that propagate through the region. However, these disturbances are grouped in periods lasting from 10 to 30 days. Such envelopes of disturbed weather and heavy rainfall are referred to as 'active periods of the monsoon'. The intervening periods of mini-drought are referred to as 'monsoon breaks'. The location of the monsoon trough and axis of heavy monsoon precipitation is generally well poleward of the position of the oceanic intertropical convergence zone (ITCZ), within which the majority of tropical oceanic precipitation occurs. For example, the rainfall associated with the South Asian monsoon falls at the same latitudes as the great deserts of the planet.

Monsoon systems are associated with colocated pairs of continents such as Asia and Australia, or continents straddling the Equator such as north-west and south-west Africa, and North and South America defining, respectively, the Asian–Australian monsoon system, the West African monsoon, and the American monsoon. Each system is different in terms of intensity and circulation characteristics. For example, the northern arm of the American monsoon is a relatively weak counterpart of the other major monsoon systems and there does not appear to be a discernible cross-equatorial component during the summer. In that sense, the North and South American monsoons may be thought of as almost separate entities. Rainfall that occurs over the continents that span the Equator (e.g., equatorial Africa and South America, and Indonesia) is not strictly monsoonal and possesses double rainfall maxima occurring with the equinoxes. Monsoon climates, on the other hand, possess a single solstitial rainfall maximum, while solstices demark the dry seasons for equatorial climates.

Basic Driving Mechanisms of the Monsoon

It is helpful to consider first a simple prototype geography that will allow us to identify the basic elements of a monsoon system. The geographical model we adopt is an oceanic planet with a continental cap extending from the subtropics to the pole in one hemisphere. After establishing the important processes that drive the monsoon for this simple geography, we will return to the consideration of local influences.

Monsoons arise from the development of cross-equatorial pressure gradients produced or modified by the following physical properties of, or processes associated with, the land–ocean–atmosphere system: differential heating of land and ocean produced by the different heat capacity of land and water; the different manner in which heat is transferred vertically and stored in the ocean and the land; modification of differential heating by moist processes; the generation of meridional pressure-gradient forces resulting from the differential heating; and the meridional transport of heat in the ocean by dynamical processes. Each of these processes and properties has to be considered relative to the rotation of the planet, and the influence of local effects such as the geography of the ocean and the land masses, and regional topography.

Differential Heating

Heat capacity differences

There is roughly a factor of 4 difference between the specific heat of water ($4218 \text{ J kg}^{-1} \text{ K}^{-1}$) and dry land (roughly $1300 \text{ J kg}^{-1} \text{ K}^{-1}$). Wet soil may have a heat capacity 30% higher than dry soil. For some net heating rate, the temperature of a mass of dry land the increment in temperature will be nearly four times greater than that of a similar mass of water. In the late seventeenth century, Halley (of Halley's comet) was the first to suggest that monsoon circulations were driven by heating gradients produced by the heat capacity differences between the land and the ocean and used his theory to explain aspects of the West African and South Asian surface monsoon winds that had been reported by explorers and traders. He also understood the role of the annual cycle of solar heating that produced the strong seasonality of the monsoon and the reversal of the circulation during the winter.

Halley had defined a basic factor that determines the existence of monsoons. However, to understand how different heat capacities produce motion and why the Halley's theory has to be expanded, it is necessary to delve deeper into the physics of the atmosphere and the ocean. If the heat flux into the surface layer is $F \text{ (W m}^{-2}\text{)}$ and if there is no heat flux out of the bottom of the layer at some depth $z = z_1 \text{ (m)}$, the heating rate of the layer will be determined by the flux divergence in the layer (eqn [1]).

$$\frac{dT}{dt} = -\frac{1}{\rho C_p} \frac{dF}{dz} = \frac{1}{\rho C_p} \frac{F_{z=0}}{\Delta z} \quad [1]$$

In eqn [1], $F_{z=0}$ is the net flux at the surface and Δz is the thickness of the layer. The surface energy balance is given by eqn [2], where I_{net} is the net radiation at the surface given by the sum of the net solar radiation, the upwelling infrared radiation, and the re-radiation from the atmosphere (the greenhouse effect), respectively.

$$F_{z=0} = I_{\text{net}} - H_s - H_e, \quad [2]$$

I_{net} is given by eqn [3], where S is the solar flux at the surface, a is the system albedo, ε is the emissivity of the atmosphere, T_g and T_a are the surface and atmospheric temperatures; H_s and H_e are the sensible and latent turbulent heat transports away for the surface as described in Figure 1.

$$I_{\text{net}} = S(1 - a) + \varepsilon\sigma T_g^4 - \sigma T_a^4 \quad [3]$$

From eqn [1] it is apparent that the heating rate of a slab will depend on the heat capacity the layer, its thickness, and the net energy flux into or out of the layer at the surface. The temperature of a motionless oceanic slab (i.e., no vertical mixing or horizontal advection) is determined by the net heating at the surface. South of the Equator, in the winter hemisphere, the slab ocean would cool by a combination of evaporative cooling and negative net radiational heating. To the north of the Equator, the ocean would heat if net radiational heating exceeded the evaporative cooling. During summer the land heats more rapidly than the adjacent ocean because of its smaller specific heat and shallow Δz . These factors easily compensate for the fact that dry land has a larger albedo than the ocean (20–40% versus about 10%). In the winter the land surface will cool much more quickly than the ocean simply because there is little available heat in the subsurface that can be made available to heat the surface on seasonal time scales because of the slowness of the diffusive processes. Given that the sensible heat exchange between the land surface and the atmosphere depends to a large degree on their temperature difference, the atmospheric column over the land will be warmer than over the ocean.

In the simple model described above, the differences between the heating rates of land and the ocean reside in their different heat capacities and densities, and the depth Δz of the slab that is defined as the depth over which the heating is spread. Over land, the Δz is very small because of the opacity of the soil to radiation, and the depth of the ‘active’ layer in which there is a discernible signal of the annual cycle is only a meter or so. This depth is constrained by the inefficiency of conductive heat transfer. If the ocean is assumed to be immobile, then its effective depth over which heating is spread may be defined as the e -folding depth of solar radiation. Here radiative transfer and the opacity of the ocean determine the effective depth. Observations suggest that the solar radiation e -folding depth is about 10 m. The ocean temperature variation will also lag the surface heating. This may be seen by setting the surface flux, $F(z = 0)$ in eqn [1], proportional to $\sin(\omega t)$. In this case the temperature variation will be proportional to $-\cos(\omega t)$, therefore lagging the forcing by a quarter period.

In summary, when the ocean is assumed to be immobile, an annual cycle of ocean–land temperature difference and meridional pressure-gradient force is achieved. Substitution of numbers into eqns [1], [2] and [3] shows that the variability of the ocean temperature is much larger than observed as long as a depth of about 10 m is used. More realistic amplitude can be achieved by ‘tuning’ the depth of the active ocean layer to be considerably greater. It turns out there are good physical reasons why we may expect a deeper active layer.

Mixing and storage of heat

So far, the fluid nature of the ocean has been ignored. In a fluid, wind forcing and gravitational instabilities formed by the

cooling of the surface layer may induce turbulence and mixing of the surface and subsurface water. Wind stress also can move a body of water horizontally, producing ocean currents that can advect heat and mass from one place in an ocean basin to another. The impact of lateral transports will be considered later. Stable layers near the surface can be produced by the freshening effect of precipitation. These fresh layers may reduce the impact of wind stirring. With these factors in mind, we can return to the consideration of the heat balances of the ocean and the land regions and the atmospheres above. These processes are shown schematically in Figure 1.

During the summer, when the net heating of the ocean surface is positive, wind-induced turbulence mixes the warm surface water downward. As long as the net surface flux of energy into the ocean is positive, wind mixing will increase the heat content (or heat storage) of an ocean column. The mixing is very effective and observations show that in the tropical ocean a constant-temperature mixed layer may extend down below the surface to depths of 50–100 m. During winter, when the net surface heating is negative, the colder surface water (formed by the negative heat balance at the surface) is mixed downward to be replaced by warmer subsurface water that had been mixed down into the ocean column during the previous summer. As long as the surface energy balance is negative, wind-induced turbulence will decrease the total heat content (i.e., reduce heat storage) in the ocean column. As turbulent mixing occurs over a much deeper layer than the e -folding depth of solar radiation, the heat absorbed in the surface layer of the ocean is spread through a depth greater than the e -folding penetration depth of solar radiation. That is, Δz is larger and the overall sea surface temperature (SST) changes are smaller in the presence of turbulence than if the ocean were immobile.

The impact of changes in heat storage on the ocean temperature is twofold. First, it moderates the SST, which in turn modulates the temperature and moisture content of the air adjacent to the ocean surface. Atmospheric turbulent mixing produced either mechanically by wind stress or by buoyancy effects extends the imprint of the SST into the troposphere. Second, the mixing processes in the ocean column produces the observed lags between the ocean temperature and the solar cycle. Land surface temperature tends to follow the solstices, although, because of moist processes, the maximum land temperature occurs before the onset of the summer rains.

The Generation of Monsoonal Pressure Gradient Forces

To account for the observed reversal of the monsoon circulation with height we require a basic driving force that changes in magnitude or reverses with height. The only force available is the horizontal pressure-gradient force. It is relatively simple to show that the horizontal pressure-gradient force between the summer and winter hemispheres may change with height and, under certain circumstance, even reverse. Eliminating density between the equation of state and the hydrostatic equation gives eqn [4].

$$\frac{\partial p}{\partial z} = -\frac{g}{R\bar{T}} \quad [4]$$

In eqn [4], $p(z)$ is the atmospheric pressure, g is the acceleration due to gravity, R is the gas constant, and $\bar{T}$ is the mean

Figure 1 Schematic diagram of the dominant physical processes determining the surface temperature over (a) land, and (b) the ocean for the transitions from (i) spring to summer and (ii) fall to winter. The radiative and turbulent fluxes are labeled relative to eqns [1], [2] and [3]. Relative e -folding depths of diffusion, solar radiation penetration, and turbulent mixing are shown as horizontal dashed lines in each section. The net incoming radiation is attenuated in the first few millimeters of soil, from where it is transferred by molecular diffusion for a few meters. Wind stress at the ocean surface causes substantial transfers of heat (upward in winter, downward in summer) between the surface layers and the subsurface ocean by inducing turbulent mixing. Successive lower tropospheric temperature profiles are also shown (marked I, II, and so on). The shading in (a)(i) shows the change in temperature if the soil is moist. The shading in (b) shows the changes in the ocean temperature profiles when heated surface water moves downward in the summer or when cooled surface water is replaced by warmer subsurface water.

temperature of the atmospheric column. Equation [4] states that the change of pressure with height is inversely proportional to the mean temperature of the column. Therefore, over the warm summer continent, the pressure will decrease with height at a lesser rate than over the cold ocean, as shown in Figure 2. The relationship can be explored by integration in the vertical through the thickness of a slab of atmosphere between heights $z = 0$ and $z = z_1$. The difference in pressure $\Delta \ln p(z)$ at height $z = z_1$ between the warm and cold columns of Figure 2 can be expressed as eqn [5], where $\bar{T}_c$ and $\bar{T}_w$ are the mean temperatures of the atmospheric columns over the heated land and the cooler ocean.

$$\Delta \ln p(z_1) = \frac{g}{R} z_1 \left(\frac{1}{\bar{T}_c} - \frac{1}{\bar{T}_w} \right) + \Delta \ln p(0) \quad [5]$$

Here, Δ refers to the difference of a quantity between the warm and cold columns along a constant height surface. From eqn [5], the condition for $\Delta \ln p(z_1) > 0$, assuming that the surface pressure difference between the warm and cold columns is zero (i.e., $\Delta \ln p(0) = 0$), is that $\bar{T}_w > \bar{T}_c$. In this case air above the surface will be forced to flow from the summer to the winter hemisphere, with mass continuity providing a lower tropospheric return flow from the winter to the summer hemisphere.

However, in general, the surface pressure over the winter subtropics is higher than the surface pressure over the heated continent, perhaps by as much as 20 hPa. In fact, as the solar heating increases over the continent, the surface pressure is observed to fall so that $\Delta \ln p(0)$ becomes increasingly negative (Figure 3). Thus the criterion $\bar{T}_w > \bar{T}_c$ is not sufficient to ensure that there will be a reversed upper tropospheric pressure gradient and a return flow to the winter hemisphere. From eqn [5], a general condition for the temperature difference for $\Delta \ln p(z_1) > 0$ in the presence of a surface pressure gradient can be found (eqn [6]).

$$\bar{T}_w > \frac{gz_1 \bar{T}_c}{gz_1 + R \Delta \ln p(0) \bar{T}_c} \quad [6]$$

These simple arguments suggest that there may be a threshold in temperature difference between the winter hemisphere and the summer hemisphere in the presence of a surface pressure gradient, before a reverse pressure gradient in the upper troposphere is established. At that stage, pressure gradients throughout the troposphere are conducive for the maintenance of a direct thermal circulation. This threshold in mean tropospheric temperature gradient may be the reason for the observed sudden onset of the monsoon over South Asia in late May or early June, at which time deep convection and heavy precipitation occur.

The post-monsoon onset circulation, in the absence of moist processes, is shown in Figure 2(a). If it is assumed that the monsoon is in steady state, the amount of heat gained by surface heating must be balanced by heat lost to space by radiative processes. For a given stratification, the vertical extent of the dry monsoon is determined by the input of heat at the lower boundary. The longitudinal extent of the circulation is determined by the time it takes for a parcel to radiate away excess heat gained at the continental surface. If radiative processes were very efficient, the longitudinal scale of the

monsoon would be very small. However, radiative processes are slow, with e -folding dissipative time scales of about 20 days. Thus, the parcel takes a considerable time to cool and a parcel in the upper troposphere travels a considerable distance while cooling.

Moist Processes and the Monsoon Solar Collector

So far, moist processes have been ignored except for their implicit inclusion in surface evaporation. Moist processes change the character of the monsoon by moistening the land surface and being the agent of strong mid-tropospheric heating through the release of latent heat over the summer continent or adjacent marginal seas.

The source for summer monsoon rainfall is water evaporated from the ocean as air flows toward the heated continent under the action of the pressure-gradient forces discussed above. Figure 4 shows the source regions of moisture for the monsoons. The figure plots the vertically averaged moisture transport, B_q , defined as in eqn [7], where $q(z)$ and $\tilde{V}(z)$ are the specific humidity and the horizontal velocity vector, respectively.

$$B_q = \int_0^\infty q \tilde{V} dz \quad [7]$$

As moisture tends to decrease exponentially above the surface, the greatest contributions to B_q come from the surface boundary layer. Moisture accumulation zones can be seen to the south of Asia extending well into the winter hemisphere during the boreal summer (Figure 4(a)) and, to a lesser extent, to the north of Australia during the boreal winter (Figure 4(b)). Even though evaporation cools the surface of the ocean, the boundary layer air flows across a gradient of increasing SST due to the net positive radiation budget at low latitudes. Consequently, the boundary layer air becomes warmer along its trajectory and, as the surface saturated vapor pressure increases, the moisture content of the boundary is elevated.

One might imagine that the dry monsoon model shown in Figure 2(a) is applicable to the monsoons during spring. Between the spring equinox and the summer solstice, the temperature of the land increases, producing a low-level pressure gradient, causing a steady advection of moist air toward the continent. Eventually, sufficient water vapor will be imported over the land so that rising motion will result in the release of latent heat and an increase in temperature of the continental atmospheric column, eventually producing a reversed pressure gradient at higher levels. The strengthening of the monsoon occurs with the rapid development of the upper-tropospheric meridional temperature gradient. The increase in columnar temperature necessary to produce the reversal (see the previous Section) is directly attributable to the release of latent heat. At this point, the acceleration of the monsoon is substantial. Surface winds that were relatively weak prior to the onset of the monsoon exceed 10 m s^{-1} at the surface when the monsoon is established. Evaporation and increased ocean mixing accompany the strengthening winds and the SST of the North Indian Ocean drops rapidly by $1\text{--}2^\circ\text{C}$.

At the time of the year when large-scale precipitation occurs, two very important transitions occur in the monsoon. First,

Figure 2 A mechanistic view of the development of the meridional monsoon circulation (a) when moist processes are ignored and (b) when moist processes are taken into account. The panels show (i) the resultant circulation, (ii) the temperature profiles, (iii) the distribution of mass in the vertical columns, and (iv) the change of pressure with height. Dashed lines in panel (i) show constant-pressure surfaces. Dashed lines in panels (ii)–(iv) denote a constant height. In both examples it is assumed that the difference in temperature of the warm and cold columns is sufficient to generate a reversing pressure gradient with height in the presence of the surface pressure gradient as described in eqn [6]. The figure is discussed extensively in the text.

Figure 3 The mean annual cycle of sea-level pressure at 20° N and 20° S along 80° E, representing the monsoon trough and South Indian Ocean, respectively.

the dry land area becomes moist, sometimes so wet that it adopts many of the characteristics of a warm shallow ocean or lake (**Figure 1**). Accompanying the surface moistening is a substantial decrease of the surface land temperature. For example, the daily maximum surface temperature of New Delhi, India often exceeds 45 °C prior to the onset of the monsoon, while during active rainy periods following the monsoon onset the surface temperature maxima are between 30 °C and 32 °C. At the same time, the intensity of the monsoon increases substantially, with both the surface and upper tropospheric winds strengthening considerably.

It would seem that the simultaneous decrease in surface temperature of the land and the cooling of the adjacent ocean with the strengthening of the monsoon would act as a negative feedback and that the monsoon strength should decrease. However, the stronger winds also cause a very large increase in the amount of water vapor imported over the continental regions. The enhanced convergence of water vapor causes the release of latent heat to increase substantially. Thus, once the monsoon strengthens, the importance of the surface temperature gradient decreases and the overall driving of the monsoon

Figure 4 Distribution of mean vertically integrated moisture transport from eqn [7] for the period (a) June–September and (b) December–February. Viewed in the context of moisture transport, the Asian–Australian monsoon system appears in both (a) the boreal summer and (b) the boreal winter as strong interhemispheric systems with moisture sources clearly defined in the winter hemisphere. Both the African summer and winter monsoons are less clearly defined. Weak moisture fluxes into north-west Africa are evident, for example, but the region is dominated by strong westward moisture fluxes associated with the Trade Wind across the Atlantic. Furthermore, the moisture fluxes associated with the North and South American monsoons appear restricted to their respective hemispheres. Only the Asian–Australian monsoon possesses a truly interhemispheric solar collector.

is taken over by the heating of the troposphere over the continents through the release of latent heat. Also, prior to precipitation, the depth of the dry circulation is relatively shallow (Figure 2(a)). However, in the moist monsoon, the circulation occupies the entire troposphere as a result of the buoyant moist parcels releasing their latent energy as they ascend to great heights (Figure 2(b)). Furthermore, the vertical lapse rate decreases, moving closer to moist adiabatic. Thus, even though the surface temperature over the land decreases, the average tropospheric temperature increases.

The monsoon may be thought of as a great solar collector. The latent heat of condensation that is released over the heated continents, and which drives the established monsoon, is the summation of the evaporation occurring at the surface of the ocean between the winter hemisphere and the heated continents (Figure 4). As the evaporation results from a net positive radiation excess at the ocean surface or from the winds driven by the SST gradients, evaporation may be thought of as the integration of the solar heating across the ocean. Thus, the latent heating of the atmosphere over the continents is the accumulation of a large fraction of the solar energy incident over the vast ocean fetch of the monsoon winds. However, the effect of this solar heating is concentrated into a relatively small region of summer hemisphere continents and the adjacent seas where precipitation occurs.

The vertical and longitudinal scales of the moist monsoon are much larger than those of the dry monsoon as may be seen by comparing Figure 2(a) and 2(b). With moist processes, there is a very large amount of heat added to the system in the vigorous moist ascent over the heated continents. This is heat accumulated during the long trajectories over the oceans: the solar collector effect. The input of energy is far larger than in the dry monsoon and, as a result, the amount of time required for the upper tropospheric flow to radiate excess heat away is much longer. Thus, the upper tropospheric pressure gradient is maintained over a much larger scale and the moist monsoon acquires a correspondingly large longitudinal scale.

The Impact of Rotation

Halley was the first to understand the fundamental role of land-sea differences in producing onshore monsoon winds. Some 50 years, later in 1735, Hadley published a paper that considered the effects of the rotation of the planet and produced a general theory for the Trade Wind regime and the monsoons.

The monsoon model we have developed so far defines a circulation system in which air parcels move about under the action of body forces whose direction and magnitude are determined by the distribution of heating. In essence, we have added to Halley's monsoon model the physics of moist processes and a more realistic view of the ocean heat capacity. However, the planet is rotating and the effects of rotation are extremely important in the equatorial regions as the Coriolis force ($f = 2\Omega \sin \phi$) changes sign and the gradient of the Coriolis force ($\beta = 2\Omega (\cos \phi)/a$) is a maximum. As monsoon motion is cross-equatorial, the dynamics of low-latitude phenomena become very important. Here we restrict ourselves to the discussion of two immediate effects of rotation on the monsoon system: the general form of the flow under

the action of a constant cross-equatorial pressure gradient on a rotating planet, and the forcing of boundary layer mass and heat transports in the upper ocean.

Impacts on the atmosphere

The horizontal equation of motion on a rotating platform may be written as eqn [8], where α (s^{-1}) is a dissipation coefficient. In the boundary layer, α^{-1} is large and has an e -folding scale of about 2 days.

$$\frac{d\mathbf{V}}{dt} = -\frac{1}{\rho}\nabla p - f\mathbf{k} \times \mathbf{V} - \alpha\mathbf{V} \quad [8]$$

Consider now a constant pressure gradient in the lower troposphere extending from high pressure in the wintertime subtropics to the low pressure over the heated continent in the summer hemisphere. Without rotation, steady flow will occur when the frictional force (proportional to wind speed) balances the pressure gradient force. From eqn [8] this balance may be written as eqn [9], where v is the meridional component of the velocity vector.

$$\alpha v = \frac{1}{\rho} \frac{\partial p}{\partial y} \quad [9]$$

The resultant flow, which is purely meridional, is depicted schematically in Figure 5(a)(i). With rotation, steady flow comes about from a balance between the Coriolis force ($f\mathbf{k} \times \mathbf{V}$ in eqn [8]), and the pressure gradient force ($\partial p / \rho \partial y$). From eqn [8], the balance may be expressed as in eqn [10]

$$f\mathbf{k} \times \mathbf{V} + \alpha\mathbf{V} = -\frac{1}{\rho} \frac{\partial p}{\partial y} \quad [10]$$

Between the high-pressure region and the Equator the flow must cross the isobars, as shown in (Figure 5(a)(ii)) because of the frictional force eventually adopting the form given by eqn [9] at the Equator. At all latitudes in this simple example, the flow is across the pressure gradient, flowing from low to high pressure. The resultant surface flow diverges out of the winter hemisphere surface anticyclone, flows across the Equator, and finally converges into the continental low-pressure region over the heated continent. In the winter, when the polarity of the pressure systems is reversed, the flow is a mirror image to the flow shown in Figure 5(a).

As discussed earlier, the flow in the upper troposphere is in the opposite meridional direction through the action of a reversed pressure gradient force that increases with height. Furthermore, compared to the surface boundary layer, the dissipation coefficient (α) is an order of magnitude smaller. The resulting flow is closer to geostrophic than the surface boundary layer flow but still cross-gradient as it spirals out of the upper anticyclone and moves westward. The trajectory that an upper-tropospheric air parcel takes is such that it will move a much greater distance in the longitudinal direction (compared to the surface flow) before it crosses the Equator and eventually descends into the winter hemisphere. The strong upper tropospheric easterlies are referred to as the Easterly Jet that extends from South Asia across East and Central Africa and attains speeds of $40\text{--}50 \text{ m s}^{-1}$. The extent of the Easterly Jet can be seen in (Figure 6(a)), which shows the mean northern hemisphere 200 hPa flow.

Figure 5 The circulation across the Equator in (a) the lower troposphere and (b) the upper troposphere on (i) a nonrotating planet, and (b) a rotating planet. Circulation is forced by a pressure-gradient force (PG) that is constant in latitude and subject to Coriolis effects (C) and frictional dissipation (F) that is assumed to be proportional to the parcel speed. The broad arrows denote the integrated Ekman mass ocean transport forced by the surface winds.

The vertical variation of the geostrophic flow is given by the thermal wind equation, which can be obtained by differentiating eqn [10] in the vertical, using the equation of state and neglecting frictional effects. This gives eqn [11], where $\bar{T}$ is the mean temperature of a layer.

$$\frac{\partial \mathbf{V}_g}{\partial z} = -\frac{g}{f\bar{T}} \nabla \bar{T} \times \hat{\mathbf{k}} \quad [11]$$

Thus if the mean temperature of a layer decreases toward the poles, then the vertical shear will be positive (e.g., lower tropospheric easterlies and upper tropospheric westerlies) in either hemisphere. However, in the monsoon regions, the shear is negative (lower level south-westerlies and upper level easterlies) so that temperature must increase towards the pole. Figure 7 plots the mean global upper tropospheric (500–200 hPa) temperature for the boreal summer and winter. During

the boreal summer, the upper troposphere of South Asia/Tibetan Plateau region is the warmest region on the planet. Importantly, the mean temperature is $>5^\circ\text{C}$ warmer than the Equator at the same longitude. During the boreal winter, a weak mean upper tropospheric temperature maximum exists in the vicinity of North Australia. The anomaly is about 1°C warmer than at the Equator. This reversed temperature gradient is sufficient to drive a weak upper tropospheric easterly jet stream over North Australia. Thermal ridges may be seen over other parts of the world (e.g., North America), but nowhere else does the temperature gradient reverse between the Equator and the pole except over South Asia and North Australia.

The Easterly Jet produced by the reversed temperature gradient has a pronounced effect on the North African monsoon. Figure 6(a) shows maximum jet speeds are attained over the central North Indian Ocean. Over central and western Africa, the flow decelerates in the exit region of the jet. The deceleration of the jet stream is important as it produces a secondary circulation over West Africa that is in the opposite sense to the local monsoon direct circulation. The circulation is produced in the following manner. Consider a parcel flowing through the Easterly Jet in geostrophic balance. From Figure 6(a) it is evident the parcel moves through the jet stream it will experience first an increase in easterly wind speed (i.e., $du_g/dt < 0$) in the entrance region, where u_g is the zonal component of the geostrophic wind. In the exit region of the jet, the easterly wind decreases in intensity (i.e., $du_g/dt > 0$). The zonal momentum equation can be written as eqn [12], where we have decomposed the meridional velocity component into a geostrophic and ageostrophic component (i.e., $v = v_g + v_a$).

$$\frac{du_g}{dt} = f v - \frac{1}{\rho} \frac{\partial p}{\partial x} = f(v_g + v_a) - \frac{1}{\rho} \frac{\partial p}{\partial x} = f v_a \quad [12]$$

Thus, in the entrance region of the jet there must be a southward displacement of the parcel. On leaving the jet, the parcel must move northward. This ageostrophic flow is shown in Figure 6(b). Over Africa, the result is the production of a secondary circulation made up of the ageostrophic northerly flow with descending air on the poleward side of the jet stream and ascending air on the equatorward side. This secondary circulation is in opposition to the monsoon meridional circulation that would have rising air over North Africa (Figure 6(c)). As a result, the secondary circulation restricts the northward extension of monsoon rainfall over the continent and may help explain why the West African monsoon is restricted to the coastal belt and why rainfall decreases so rapidly over the Sahel and the Sahara. On the north side of the entrance region of the Easterly Jet, the South Asian monsoon circulation is enhanced by the secondary circulation. This enhancement occurs in the Bay of Bengal region and perhaps explains the existence of the most intense rainfall in the Asian monsoon.

It is paradoxical that the limitations on the poleward extent of the African rainfall are the result of the South Asian monsoon rainfall falling so far to the north. Reasons for the anomalous latitudinal location of the South Asian monsoon rainfall will be discussed in the next section. These are the same reasons that determine the longitudinal extent of the jet stream and hence the limit of its effect on African rainfall.

Figure 6 Impacts of the large monsoon heating over South Asia. (a) The upper tropospheric circulation. Note the extent of the Easterly Jet that commences over the north-eastern Indian Ocean and extends out across the Atlantic Ocean. (b) The secondary circulation associated with the entrance and exit regions of an easterly jet stream. Note that the ageostrophic flow produces a northward deflection of the winds that is consistent with subsidence on the northward side of the jet and rising surface pressure. (c) Schematic diagram showing the secondary circulation in opposition to the monsoon meridional cell.

Figure 7 Distribution of the mean upper tropospheric temperature averaged between 200 and 500 hPa for the boreal summer (JJA) and winter (DJF). Note the two locations where the mean temperature is warmer than the equatorial temperature: over the Tibetan Plateau during the boreal summer and to the north-east of Australia in the austral summer.

Impacts on the ocean

Rotational effects are very important in the ocean and play a key role in determining both the overall character of the annual cycle of the monsoon and its interannual variability. The heat balance of the ocean mixed layer may be written as eqn [13].

$$C_w \frac{dhT}{dt} = F_{z=0} + F_{adv} \quad [13]$$

Here h and T are the thickness and temperature of the mixed layer, and $F_{z=0}$ is defined in eqn [2]. F_{adv} refers to the advection of heat in and out of the column. Equation [9] allows for the horizontal advection of heat by ocean currents. The depth of the mixed layer is determined, to a large degree, by wind-forced turbulent mixing as discussed earlier.

Observations in the North Indian Ocean suggest that the advective term may be important. In the period between March and May, the average net surface flux into the North Indian Ocean is $>100 \text{ W m}^{-2}$. However, the SST increases by only about 2°C during this period compared to about 9°C that would be expected if $F_{adv} = 0$. It is important to understand the reason for this SST modulation, as the monsoon would be very different if the temperature of the North Indian Ocean were much warmer. Modulation might occur by either heat storage increases (by deepening of the mixed layer) or by the horizontal advection of heat away from the summer hemisphere. As it turns out, both processes are important.

The instantaneous northward flux of heat across the Indian Ocean between two meridians x_1 and x_2 and the change in heat storage in the ocean column are given by eqns [14] and [15].

$$F_{adv} = \rho_w C_w \int_{x_2}^{x_1} \int_z^0 (HvT) dx dy dz \quad [14]$$

$$S_Q = \rho_w C_w \int_{x_1}^{x_2} \int_{y_1}^{y_2} \int_z^0 (HT) dx dy dz \quad [15]$$

Here ρ_w and C_w represent the density and specific heat of sea water, and the coordinates x , y , and z represent longitude, latitude, and depth, respectively. Figure 8 shows the total cross-equatorial flux of heat flux by oceanic processes from eqn [14], the change in oceanic storage of heat of the entire Indian Ocean north of the Equator from eqn [15], and the net surface heat flux into the North Indian Ocean from [2]. In addition, the atmospheric flux of latent heat across the Equator is also plotted. Compared to the magnitude of the net surface heat flux into the ocean (about 0.5 PW), the changes in storage and the heat flux across the Equator are much larger, with amplitude swings of $\pm 2 \text{ PW}$ through the annual cycle. Clearly, the surface heat flux is not driving either meridional heat transport or changes in heat storage. A large part of the changes in storage occur through cross-equatorial transports of heat. Figure 8 shows that transport has an extremely large annual cycle, with a maximum northward transport occurring in winter and early spring and a reverse transport occurring in the summer. Finally, it should be noted that the atmospheric latent heat flux is almost exactly out of phase with, and roughly equal in magnitude to, the lateral oceanic heat transport across the Equator. Clearly, the ocean and the atmosphere are working in

Figure 8 (a) Annual cycle of the meridional ocean heat transport across the equator, changes in the surface heat flux integrated over the North Indian Ocean, the change in total heat storage in the North Indian Ocean (NIO), and the atmospheric meridional transport of latent heat across the Equator. All quantities are averaged across the Indian Ocean. (b) Time-latitude plot of the cross-equatorial ocean flux of heat. All units are in PW (10^{15} W).

tandem in some manner to determine the overall heat budget of the monsoon.

If the atmospheric and oceanic components of the monsoon are coupled, what are the processes responsible for the coupling? The fundamental clue to understanding the coupling comes from noting that the majority of mass and heat transport in the ocean is wind-driven. Transport is a combination of geostrophic and Ekman transport such that $F_{adv} = F_{geos} + F_{Ek}$. The meridional Ekman transport is especially interesting and may be written as in eqn [16], where τ_x is the zonal wind stress and T' is the degree to which the temperature of the upper ocean is warmer than the lower ocean.

$$F_{Ek} = C_w \int \frac{-\tau_x}{f} T' dx \quad [16]$$

In the Northern Hemisphere ($f > 0$), the transport will be southward if the winds are westerly ($\tau_x > 0$) and northward for easterly winds ($\tau_x < 0$). As $f < 0$ in the Southern Hemisphere, the reverse associations are true. More generally, vertically averaged oceanic Ekman transports are to the right of the surface wind in the Northern Hemisphere and to the left of the wind in the Southern. Thus, in a monsoon system, the heat transport will be southward in both hemispheres in the boreal summer and northward in the winter hemisphere, as shown in Figure 5(a). This means that the overall oceanic heat transport has the opposite sign to the atmospheric heat transport that is in the direction of the lower tropospheric divergent wind. The overall effect of the wind-driven oceanic heat transports is to cool the SST in the summer hemisphere and warm the SST in the winter hemisphere, thus reducing the cross-equatorial SST gradient.

Finally, it should be noted that Ekman transports are not really applicable very close to the Equator as the 'spin-up' time for an Ekman transport to begin after winds goes as the inverse of the Coriolis parameter. At the Equator the spin-up time would be infinite. However, the approximation is valid a few

degrees from the Equator and ocean models show a smooth transition of heat transport across the Equator that matches the Ekman transport to the north and south.

Regional Effects

In reality, the geography of the monsoon regions is far more complicated than the idealized model discussed so far. Each monsoon region possesses different land-sea distributions and topography. It might therefore be expected that the monsoon flows will have strong regional character. Nowhere is topography more important than around the Indian Ocean basin where the East African Highlands and the Tibetan Plateau complex extend along the eastern boundary of the basin and over South Asia, respectively.

The meridionally oriented East African Highlands act as a mechanical barrier to the South Indian Ocean south-east trades and concentrate the low-level flow intercepting the barrier crossing the Equator as an intense low-level flow called the Somalia Jet. Wind speeds in the core of the jet exceed $20\text{--}25 \text{ m s}^{-1}$. The impact of the East African Highlands is shown schematically in Figure 9. The jet stream drives a strong cross-equatorial Somalia Current and farther up the coast produces intense coastal upwelling that is associated with the $3\text{--}4^\circ\text{C}$ drop in SST in the eastern Arabian Sea compared to $1\text{--}2^\circ\text{C}$ over the entire North Indian Ocean.

During the spring and summer, the role of the Tibetan Plateau complex thought to be thermal, acting as an elevated heat source rather than as a barrier. To understand the concept of an elevated heat source, one needs to consider the heat balance on the surface of the plateau and the heat balance of the free atmosphere at the same elevation but away from the plateau. During spring and summer, the interception of radiation on the plateau causes a transfer of sensible heat and latent heat to the atmosphere of about 100 W m^{-2} compared to a much smaller value in a layer of atmosphere over the plains to

Figure 9 (a) Horizontal section of the Somalia Current at 1 km showing its lateral extent. Region north of the equator is a region of strong ocean upwelling forced by the wind. (b) Latitude–height section of the Somalia Jet along the equator. Units are m s^{-1} .

the south. The heating of the plateau produces a localized heating anomaly. **Figure 10** shows the heating that occurs throughout the troposphere at 10° N, 20° N, 30° N, and 40° N at 80° E after May 1. During the boreal winter, there is no evidence of heating over the plateau. Instead, the topography acts as a mechanical barrier to the strong boreal winter westerlies.

To a large degree, the Tibetan Plateau is major factor determining the character of the South Asian summer monsoon. The location of the elevated heat source to the north of 25° N is sufficiently strong to produce rainfall well into the subtropics, which, on a global perspective, are usually regions of low rainfall and deserts. The location of the upper tropospheric anticyclone is determined by Tibetan Plateau, which, in turn, sets the position of the upper tropospheric Easterly Jet and the region influenced by the secondary circulations in the exit region (**Figure 6**).

Regulation of the Monsoon System

One of the interesting features of the South Asian monsoon is its relative constancy from year to year. For example, the mean precipitation over the Indian subcontinent is 852 mm with a standard deviation of 84 mm. These statistics represent a high-rainfall region with very small variability about the mean. Furthermore, prolonged droughts or floods (i.e., mean summer rainfall outside the range of 852 ± 84 mm) are very rare. Between 1870 and 1998 there were 17 flood years and 22 drought years. Equally interesting is the lack of prolonged anomalies. Excessive rainfall occurred in successive years only twice (in 1892–94, and 1916–17), while deficient rainfall has occurred in successive years three times (1904–05, 1965–66, and 1985–87). The El Niño Southern Oscillation (ENSO) phenomenon explains about 40% of the variance, with El Niño

often being associated with drought and La Niña with flood. Also, it has been noted that there are periods where there is strong biennial trend in the rainfall record, with strong and weak monsoon years occurring successively. Overall, it would seem that the monsoon is regulated in some fashion to fall within rather narrow limits of variability. In the following paragraphs, it will be suggested that regulation of monsoon intensity occurs through the interaction of the ocean and the atmosphere in the manner introduced described under 'The Impact of Rotation'.

Regulation of the Monsoon Annual Cycle

Figure 11 shows a schematic of the atmospheric circulation and corresponding ocean heat transport for the boreal summer and winter. The impact of the wind-driven ocean heat transport is to homogenize the SST gradient across the Equator, lowering it in the summer hemisphere and warming it in the winter hemisphere. The reduction of the SST gradient will have two major impacts. First, the cross-equatorial pressure gradient will be reduced, which will have the effect of reducing the intensity of the monsoon winds. Second, the reduced SST in the summer hemisphere reduces the saturated vapor pressure of an air parcel approaching the continental region. As the SST is very warm, small changes in the SST will invoke large changes in the saturated vapor pressure, as determined by the nonlinear Clausius–Clapeyron equation. The reduced monsoon winds will lower the convergence of moisture into the continental regions. In tandem with the reduced saturated vapor pressure this reduces the release of latent heat in the precipitating regions. The overall impact of the two processes is to reduce the amplitude of the monsoon annual cycle. Without ocean heat transports, the SST extremes would produce a monsoon that would be very different from that which is observed today and would quite likely be much wetter.

Figure 10 Time section of the change in atmospheric temperature over the Tibetan Plateau based on temperatures at 1 May.

Figure 11 (a) A regulatory model of the monsoon for the annual cycle. Climatological lower tropospheric winds (solid black lines) are shown for summer (left panel) and winter (right panel). Blue dashed lines show the direction of Ekman mass transports which are to the right of the wind in the northern hemisphere and to the left in the southern hemisphere. Given the general sea-surface temperature gradient, heat is transported from the summer hemisphere to the winter hemisphere in both seasons. From Figure 8 it can be seen that these heat transports can be substantial enough to change the temperature of the entire North Indian ocean by 2–3°C. (b) Summer representations of the surface wind in strong and weak monsoon years. In a strong year, the Ekman transport will be large while in a weak year it will be smaller. Thus during a strong year the northern Indian Ocean will cool at a greater rate than during a weak year. Given that a strong monsoon is usually preceded by warmer than average sea-surface temperatures in the Indian ocean, a strong monsoon year is often followed by a weak monsoon and vice versa.

It is important to note that the annual cycle of oceanic heat transports, as described above, is a phenomenon that is restricted to regions that have strong cross-equatorial pressure gradients and a surface flow from the winter to the summer hemisphere. For example, the Pacific Ocean is characterized by a Trade Wind regime that converges into the western Pacific from both hemispheres. The Ekman transports of mass and heat are away from the tropics in both hemispheres: to the right of the north-easterly Trades and the left of the south-easterly Trades. The ocean heat transport produced by the Pacific Trade Winds is probably important in regulating the surface temperature of the Pacific warm pool. However, the strong

seasonality and change in sign of the heat transport is restricted to the Indian Ocean monsoon regime.

Regulation of Monsoon Interannual Variability

Imagine that, for some reason, that the SST in the northern Indian Ocean during spring was higher than normal. Such alterations to the climatology could be imposed by external factors such as ENSO, anomalous winter or spring snowfall over Eurasia, or the result of stochastic processes. Warmer than average SSTs would lead to a stronger than average monsoon winds. In fact, there is observational evidence for the

Figure 12 Time sections of the oceanic cross-equatorial heat flux, the net surface heat flux into the North Indian Ocean, and the change in ocean heat storage in the North Indian Ocean for the years 1983–89 as computed from an intermediate ocean model driven by observed winds and fluxes: (a) 5-day averages, (b) annual averages. 1987 and 1988 were weak and strong monsoon years associated, respectively, with El Niño and La Niña.

relationship. Indian Ocean SSTs during the previous winter and early spring correlate positively with the strength of the ensuing monsoon. Overall, the same processes that regulate the annual cycle of the monsoon ensure that the anomalous imposed conditions (e.g., high SST, weak winds) are eradicated.

For the case of higher than average springtime North Indian Ocean SSTs, the meridional pressure gradient would tend to be stronger and the near-surface saturated vapor pressure higher, causing a stronger than average monsoon to develop. A strong monsoon with greater than average winds would (1) cause deep mixing and increase the ocean storage of heat, and (2) drive stronger than average southward wind-driven oceanic heat transports. The impact of the strong monsoon would be to cool the North Indian Ocean so that the SSTs during the following winter would be lower than average. In turn, these lower SSTs would produce a weaker than average monsoon in the following spring and summer. Associated with the weaker than average monsoon winds would be a lowering of the southward heat transport.

Figure 12 shows an example of the monsoon interannual regulation process at work. In 1987 a strong El Niño occurred and was followed in 1988 by an equally strong La Niña. In 1987 the South Asian monsoon was weak, with Indian summer rainfalls 17% below normal. In 1988 the monsoon was strong, with rainfall over India 13% above normal. The figure shows

a time section of the annually averaged northward oceanic heat transport for these two years calculated using a stand-alone ocean model driven by observed winds. Figure 12 plots annually averaged values. The long-term average cross-equatorial heat transport is about -0.2 PW which matches the climatological net surface heating over the North Indian Ocean. However, during the weak monsoon year of 1987, the net surface flux was slightly higher and, associated with the weaker monsoon winds, the cross-equatorial ocean heat transport reversed from the climatological value of -0.2 PW to $+0.2$ PW. During the following year, the net surface flux into the North Indian Ocean was reduced while, responding to the much stronger monsoon winds, the oceanic heat transport was twice the long-term mean value of -0.2 PW at -0.45 PW. The two years 1987 and 1988 illustrate the manner in which the monsoon system responds to forcing anomalies and returns the system to equilibrium.

Summary

A rather different picture of the monsoon has been presented. Rather than describing the monsoon as a gigantic sea breeze driven by the differential heating between the ocean and land, a self-regulating system has been introduced in which dynamic aspects of the ocean play critical roles in modulating the strength of the monsoon. On this view, it is clear that if the variability of the monsoon is to be predicted, it will be necessary to consider the system as a fully coupled interactive system. As such, the numerical models that will be used to simulate and predict monsoon behavior will have to have interactive oceans.

Introduction

The word ‘monsoon’ is derived from the Arabic word *mausam*, which means season. In monsoon regions, the change of season is accompanied by a reversal of the prevailing wind direction and abrupt changes in rainfall patterns. The most pronounced monsoon climate is found in the Asian–Australian region. Other regions that exhibit monsoonal characteristics include the maritime continent, western Africa, central America, south-western North America, and South America. These regions are often adversely affected by severe droughts and floods caused by the strong year-to-year-variability in monsoon rainfall. During the summer of 1997, southern China experienced severe flood while northern China was gripped by one of the driest seasons on record. In the summer of 1998, a monsoon depression in Bangladesh devastated the country, causing major floods in the Ganges and the Brahmaputra river, displacing over 30 million people, and resulting in property and agricultural loss of over \$US 3.4 billion. In the same summer, a flood of biblical proportion ravaged the Yangtze River basin and northeastern China, displacing over 220 million people, inflicting a huge economic loss of over \$US 12 billion. Understanding and predicting monsoon variability is therefore vitally important for benefit of society.

Scientists have long suspected that there is a connection between monsoon rainfall variability and components of the global circulation system. G. T. Walker in the 1920s found that the Indian monsoon rainfall anomalies may be foreshadowed by seasonal surface pressure variations over several ‘strategic’ points remote from India. Of the many planetary-scale patterns found by Walker, the most important is the Southern Oscillation (SO), which was described as ‘a swaying of pressure on a big scale backwards and forwards between the Pacific Ocean and the Indian Ocean’. However, his effort to translate the monsoon–SO relationship into seasonal and interannual prediction of Indian monsoon rainfall was largely

unsuccessful. Several decades later, Bjerknes first suggested that the SO as found by Walker is closely linked to El Niño, Bjerknes work and subsequent research have led to the development of various empirical monsoon forecast schemes based on the El Niño–Southern Oscillation (ENSO). However, results are mixed, because even though ENSO may be important in influencing monsoon rainfall variability, there are a large number of factors that may confound or limit monsoon predictability. With the advances in our understanding and prediction of ENSO, there is now renewed interest in reexamining the monsoon–ENSO relationship and its possible utilization for monsoon prediction. The discussion here will focus mainly on the most pronounced monsoon system, the Asian–Australian monsoon (AAM), unless specified otherwise.

The Basic Relationship

Figure 1 shows the time-series of all-Indian summer rainfall (June–September) from 1871 to 1998. Large interannual variability can be seen. There also appears to be interdecadal modulation of the amplitude of the anomalies. Relatively small anomalies are found in the 1880s–90s, the 1920s–40s, and in the 1990s. Large anomalies are found in the 1900s–20s, 1960s–80s. As indicated by the color shading, the Indian monsoon is generally below normal preceding the peak of a warm sea surface temperature (SST) event (El Niño) and above normal preceding a cold event (La Niña). However, there are warm or cold events that produce very weak signals or even anomalies of the opposite sign. Most important, a large number of major rainfall anomalies are not related to either El Niño or La Niña. Similarly relationship can be found for the austral monsoon (not shown). Hence, not all monsoon floods and droughts can be explained by ENSO.

Figure 1 Time-series of All-India rainfall anomaly, normalized by standard deviation, with respect to the base period 1871–1998. Red bars indicate years with peak El Niño warming in following winter, and blue bars indicate years with peak La Niña cooling in following winter.

Table 1 Rainfall anomaly statistics for all-India summer rainfall and northern Australia summer rainfall, based on approximately 124 years of data

Rainfall	All India		Northern Australia	
	Total	El Niño (La Niña)	Total	El Niño (La Niña)
Below average	53	24 (2)	49	20 (4)
Above average	71	4 (19)	58	5 (17)
Drought	22	11 (2)	18	9 (0)
Flood	18	0 (7)	17	2 (5)

From Webster et al. (1998) Monsoon: processes, predictability, and the prospects for prediction. *Journal of Geophysical Research – Oceans* 103: 14451–14510. Reproduced by permission of American Geophysical Union.

Table 1 summarizes the monsoon rainfall statistics in relationship to the occurrence of El Niño and La Niña for a multidecadal period, for all of India and for northern Australia. During the 124-year period, out of the 53 events classified as below average, 24 events were associated with El Niño. Only 2 were associated with La Niña. For 71 above-average events, 4 belong to the El Niño group and 19 to the La Niña group. Altogether, El Niño explains fewer than 50% of the total below-average events and La Niña fewer than 30% of the above-normal events. For extreme events, the statistics shown in **Table 1** convey the same message. Out of the 22 extremely deficient-rainfall events, 11 were associated with El Niño and only 2 were found in La Niña. Conversely, for

extreme excessive-rainfall events, 7 out of 18 were found in La Niña, and none were associated with El Niño. For northern Australia, the statistics are very similar. Obviously, the relationship is far from perfect, but it is clear that in some fundamental way the two phenomena are related.

Spatial Patterns

To understand the physical underpinnings of the basic ENSO–monsoon relationship, we turn to the spatial distribution of rainfall and large-scale circulation anomalies associated with ENSO. **Figure 2** shows the seasonal climatologies (long-term mean) and composites of seasonal mean anomalies of rainfall and surface wind over the Asian–Australian monsoon region for December–January–February (DJF) and June–July–August (JJA) respectively. The anomalies are shown as the difference between composites of El Niño and La Niña. Climatologically, the boreal summer monsoon is associated with centers of heavy rainfall anchored to the west coast of India, the Bay of Bengal, Indo-China and the South China Sea/Western Pacific region (**Figure 2(a)**). The low-level circulation is dominated by a large-scale anticyclonic (clockwise in the Northern Hemisphere) gyre circulation over the Indian Ocean. This anticyclone gives rise to a strong low-level westerly flow across the Indian subcontinent and Indo-China, subsequently turning northward into East Asia and Japan. A dominant low-level anticyclonic circulation, known as the Subtropical High is located over the subtropical western

Figure 2 Climatology of rainfall and 850 mbar wind streamlines for (a) JJA, (c) DJF. Rainfall and 850 hPa streamline anomalies (warm events minus cold events) for (b) JJA and (d) DJF. Unit of rainfall in mm per day.

Pacific, with prevailing easterlies in its southern flank, between 10° S and 10° N. The westerlies and easterlies converge over the South China Sea/Philippines region, coinciding with the zone of heavy precipitation in this region. During El Niño (opposite for La Niña), enhanced rainfall and low-level westerlies are found over the equatorial central Pacific (Figure 2(b)). Reduced rainfall is found over the maritime continent and the subtropical western Pacific in both hemispheres. The rainfall pattern between 10° S–10° N over the Indian Ocean and the Western Pacific has been referred to as a ‘rainfall dipole’, which is one of the many key signatures of El Niño. Note that the responses over the monsoon land regions are not very well defined, compared to their oceanic counterparts. In particular, over the Indian subcontinent the signal is mixed. Over the Indian Ocean, the anomalous easterly flow between the equator and 15° N signals a weakening of the Indian Ocean gyre circulation. The rainfall dipole, which is made up of general suppression in rainfall (sinking motion) over the monsoon region and enhancement of rainfall (rising motion) in the equatorial central Pacific, is due to the eastward shift of the Walker circulation (*see Tropical Meteorology and Climate: Walker Circulation*) during El Niño.

During the austral summer, December–January–February (DJF), the zone of heavy rainfall shifts south of the Equator to the maritime continent, northern Australia and oceanic regions further east, near the dateline (Figure 2(c)). The large-scale circulation features low-level easterlies over the Northern Hemisphere western Pacific and much of the Indian Ocean just north of the Equator. Over the far western Pacific and the Indian Ocean, the flow turns southward and then eastward into the Southern Hemisphere, culminating in a belt of westerlies from the eastern Indian Ocean to 160° E. During an El Niño, rainfall anomaly occurs again in the form of an east–west dipole, with increased rainfall over the equatorial central Pacific and suppressed rainfall over the far western Pacific/maritime continent. In addition, a broad region of enhanced rainfall is found over the central and western Indian Ocean and an area of reduced rainfall over the eastern equatorial Indian Ocean. Together, these rainfall anomalies form a secondary dipole over the Indian Ocean. While the Indian Ocean dipole appears as part of the signal of ENSO, it has been suggested that the Indian Ocean dipole may also arise from regional coupled ocean–atmosphere processes that are independent of ENSO. Accompanying the anomalous rainfall are anomalous low-level westerlies over the central Pacific and easterlies over far western Pacific and Indian Ocean, consistent with the eastward shift of the Walker circulation during El Niño.

The relationship between rainfall over India and northern Australia and El Niño/La Niña noted earlier can be seen only as elements of a much larger shift in the tropical rainfall and circulation pattern. Note that composite pictures like those shown in Figure 2 only bring out common features for different El Niño/La Niña events, the actual rainfall anomalies may vary greatly regionally and for individual events.

Factors Affecting Monsoon–ENSO Relationships

Regional Ocean–Atmosphere Processes

Recent studies have shown that in addition to the basin-scale monsoon–ENSO mode associated with the shift of the

Walker circulation, there are intrinsic modes of variability in the monsoon–ocean–atmosphere system that are not directly connected with ENSO. These modes stem from regional coupled ocean–atmosphere processes in the Indian Ocean, the western Pacific, the South China Sea and Indonesian waters. The regional anomalies can amplify, oppose, and/or modulate ENSO-induced direct changes as the Asian–Australian monsoon responds and adjusts to the ENSO forcings. The regional ocean–atmosphere process regulates the SST and rainfall covariability in the monsoon region, through fluxes of heat and momentum at the ocean–atmosphere interface. This regional coupling covers a wide range of timescales ranging from the intraseasonal to interannual and beyond (see the discussion of intraseasonal variability later).

Snow Cover

A major factor that may confound the monsoon–ENSO relationship is the impact of snow cover on the evolution of the monsoon. In a report that dates back to the nineteenth century, Blanford in 1884 first showed that the strength of the Indian summer monsoon may be affected by snow cover over the Himalayas. There is now observational evidence suggesting that persistent winter snow cover over the Tibetan Plateau may delay or weaken the monsoon during the following summer. Increased snow cover increases the surface albedo, reflecting more solar radiation from the land surface. Heat energy that would otherwise be used to heat up the land will be used to melt the extra snow. As a result, the land surface heats up more slowly during the spring and summer, reducing the land–sea contrast and therefore weakening the monsoon. Conversely, reduced snow in the previous winter may lead to enhanced monsoon rainfall. However, while Eurasian snow cover changes may be related to internal atmospheric processes, increased snow cover over Eurasia may not be independent of ENSO on the interannual timescale.

Land–Atmosphere Hydrological Feedback

Land–atmosphere processes can affect monsoon and monsoon–ENSO relationship by altering the energy and water cycles within the monsoon regions, through surface heat fluxes and hydrological feedback mechanisms, as illustrated in the schematics in Figure 3. For example, if the soil moisture content of the Asiatic land mass is abnormally high during the start of a monsoon season, land surface evaporation will be increased. This will lead to increased moistening of the atmospheric boundary layer, more unstable air masses and hence more convection and rainfall, resulting in a positive feedback, leading to further moistening of the land region. However, the cloudy sky condition stemming from enhanced convection will shield and reduce the amount of solar radiation reaching the land surface, causing the land to cool. As the land mass cools, the resulting decreased land–sea thermal contrast can only support a weaker large-scale monsoon circulation, with reduced monsoon rainfall. This results in a negative feedback, halting further increase in soil moisture. These feedback mechanisms are dependent not only on local processes but also on the remote forcing such as forced large-scale descent or ascent over the AAM region by ENSO. The large-scale vertical

Figure 3 Schematic showing elements of land–atmosphere water and energy cycle feedback for the Asian–Australian monsoon (AAM) region. Negative feedback links are denoted by the symbol NF. The symbols used are for precipitation (P), evaporation (E), soil moisture (S), cloudiness (CL), ground temperature (T_g), surface long-wave radiation (LW_{stc}), surface short-wave radiation (SW_{stc}) and sensible heat flux (SH). The sign of the anomalies indicate the possible feedback mechanisms for a persistent cool, wet monsoon climate when the ENSO forcing favors upward motion over the AAM region.

motions provide a strong control on atmospheric stability and initiation of convection. Even though the ENSO remote forcing has relatively slow timescales, its impact may be sufficient to tip the delicate balance of the aforementioned local feedback processes, causing either the persistence of a given climate state or transition from one state to the other.

Intraseasonal Variability

One of the key characteristics of the monsoon is the presence of a rich spectrum of intraseasonal variability. These include quasi-periodic oscillations of 30–60 days or 10–20 days and transient waves of 3–5 days. The intraseasonal variabilities are generated by internal atmospheric dynamics but strongly modified by sea surface temperature and land surface processes. They are responsible for the modulation of monsoon onsets, breaks, and evolution regionally. Intraseasonal variabilities, especially those in the lower-frequency end of the spectrum, can have strong impacts on the seasonal mean monsoon climate. Over different regions, they can either strengthen or weaken the direct influence by ENSO on the monsoons. It has been suggested that, the near normal monsoon rainfall over India during the strong El Niño of 1997–98 may be due to the effects of pronounced intraseasonal variability, which brought copious rainfall to many parts of India in spite of the tendency of ENSO to weaken the AAM.

Biennial Variability

Rainfall records in many monsoon regions show a strong biennial tendency, i.e., a strong monsoon followed by a weak monsoon, and vice versa. Some aspects of this tendency can be discerned from Figure 1. The origin of the biennial tendency in the monsoon is still unclear, but it may be related to local air–sea interaction as well as basin-scale coupled processes. Coincidentally, a strong biennial tendency has also been

found in ENSO cycles. Except for the different timescale, the evolutionary features of the biennial oscillation in sea surface temperature, sea level pressure, wind, and precipitation are very similar to those of ENSO. Recent studies have suggested that strong monsoon–ENSO interactions may be manifested in a strong biennial tendency in ENSO cycles. Because the monsoon wind forcings have strong seasonality, and their directions and magnitudes are strongly tied to ENSO, it is possible that monsoon wind forcings may induce a biennial time scale in ENSO.

Interdecadal Variability

Because of multiple contributing factors, the relationship between monsoon and ENSO is likely to be nonstationary. Webster and colleagues showed that during the late 1800s and early 1900s the correlation between Indian rainfall and the Southern Oscillation Index (SOI) was relatively high (~ 0.6), but in the 1920s–40s the correlation dropped to less than 0.2–0.3. It rose again to 0.5–0.6 in 1960s–80s. In more recent decades, there is again a sharp decline in the correlation to less than 0.2. These changes appear to correlate with changes in sea level pressure and large scale circulation patterns. The interdecadal modulation of monsoon–ENSO relationship has led some authors to suggest that the recent weakening of the relationship may be linked to changes in the structure of ENSO, perhaps due to global warming. However, these assertions should be treated with extreme caution, because of the uncertainty in the historical data records and the sensitivity of the analysis to long-term trends.

Future Prospects

Year after year, occurrences of devastating monsoon-related droughts and floods serve as a reminder that improved

prediction of the monsoon rainfall is paramount for the well-being of millions living in the monsoon regions. Today, monsoon prediction is still a very challenging problem. With the better understanding of monsoon–ENSO interaction, and its relationship with other contributing factors, scientists are hopeful that they are a step closer to better understanding the causes and the predictability of monsoon rainfall anomalies and to devising better monsoon prediction schemes.

Tropical Climates

S Hastenrath, University of Wisconsin, Madison, WI, USA

Synopsis

Radiative forcing and diurnal and local circulations are crucial in the tropical circulation and climate system. On the large scale there is prevailing subsidence and high surface pressure in the subtropics, in the lower layers heat and moisture transport equatorward, and convergence, ascending motion and abundant rainfall in the equatorial zone. Seasonality is very pronounced in the monsoon regions of southern Asia and Africa. Equatorial zonal circulations develop over the oceans. Interannual variability of circulation can have severe climatic implications in some tropical regions.

Introduction

For the understanding of the global climate system, processes in the tropics merit particular attention. Research on the low latitudes in recent decades has developed an increasing appreciation for the large time and space scales, and has turned its focus on the dynamics of climate, as compared with the emphasis on weather events and smaller-scale processes which prevailed throughout the earlier part of the past century. 30° N and 30° S are plausible approximate boundaries of the tropics, considering the location of the subtropical high-pressure cells; the domain of net radiative heat gain at the top of the atmosphere; the prevalence of diurnal over the annual cycle of solar radiation and temperature; and the latitudinal variation of the Coriolis parameter.

Diurnal and Local Processes

In the tropics, day-periodic processes and local to meso-scale circulations are much more vigorous than in higher latitudes. As a result of radiation geometry, the amplitude of the diurnal cycle of insolation and temperature is much larger than the annual cycle. Over the open ocean, the cloudiness–rainfall maximum occurs commonly in the late night to early morning hours. Over the tropical land areas, land- and seabreeze and mountain circulations dominate the diurnal march of cloudiness, rainfall, and weather. Anabatic flows lead to an afternoon maximum on the mountains, with compensating subsidence and clearing over the basins. Rainfall in the basins occurs with some preference at night. At the coasts, a land breeze may interact with large-scale flow to produce a convergence and rainfall maximum in the latter part of the night. Large inland lakes experience lower-tropospheric convergence, cloud cover and rainfall during the night, and subsidence and clear skies during the day. Diurnal mass exchanges between highlands and adjacent plains on the scale of the hundreds of kilometers may be responsible for the suppression of daytime convection and the origin of a nighttime cloudiness–rainfall maximum over the lowlands.

The marked diurnal and local controls in the tropics are important factors for the regional climates and the large-scale circulation. Thus in many tropical regions the annual rainfall distribution can be appreciated only from the interaction between diurnal factors, local circulations, and the large-scale

flow. The resultant spatial pattern of latent heating is in turn essential in the driving of the circulation on a planetary scale.

Planetary Context

The zonally averaged planetary scale circulation of the tropics consists of an easterly wind regime bounded by the anticyclonic axes of the subtropical highs and the two thermally direct mean meridional circulation cells (Hadley circulations), sketched in Figure 1. The tropical atmosphere is a source of westerly absolute angular momentum and of kinetic energy. The required poleward transports in low latitudes are performed primarily by the mean meridional circulation, while beyond the fringe of the tropics eddy mechanisms assume the dominant role. The intensity of the mean meridional circulation and the associated production and export of kinetic energy are largest in the respective winter. In mechanical terms, the tropical atmosphere thus is instrumental in the maintenance of the global circulation.

Further important constraints of the general circulation relate to the budgets of heat and moisture, and these can be adequately treated only for the atmosphere–hydrosphere

Figure 1 Schematic sketch of planetary high- and low-pressure belts and mean meridional circulations.

Figure 2 Annual mean meridional transports within the coupled atmosphere–hydrosphere system (dashed), within the oceans (solid), and within the atmosphere (dash-dotted). Positive values indicate northward heat flux. Adapted from Hastenrath, S., 1995. *Climate Dynamics of the Tropics*. Kluwer, Dordrecht, Boston, London.

system as a whole. Fundamental to the heat budget of the planet Earth is the net radiation at the top of the atmosphere. This defines the total required poleward transport of heat in the coupled atmosphere–ocean system. Through the analysis of atmospheric transports (from upper-air sounding) and of the heat fluxes across the ocean surface (from ship observations) this has been partitioned into the contributions from the atmosphere and the hydrosphere, respectively. Results are presented in **Figure 2**. The required total poleward transport in the combined system is largest around 30° N and 30° S. The atmospheric transport is largest in the mid latitudes. In the tropics, the oceans accounts for about half the total poleward transport, with the largest amounts around 30° N and 20° S. The transport of water vapor and latent heat in the atmosphere is related directly to the meridional pattern of precipitation and evaporation from the surface. In the mid latitudes transient eddies account for most of the poleward transport of the atmospheric water vapor. By contrast, in the tropics the mean meridional circulation carries water vapor and latent heat equatorward, and this transport is concentrated in the surface layer. Latent heat release and precipitation are concentrated in the equatorial zone, from where sensible heat and geopotential energy are exported poleward in the upper portion of the mean meridional circulation.

Regional Circulation Systems

Complementing the latitude-mean sketch in **Figure 1**, **Figure 3** portrays the spatial patterns of the lower- tropospheric circulation during the extremes of the annual cycle. Persistent features throughout the year are the three subtropical highs over the southern oceans, the two highs over the North Pacific and North Atlantic, and the enclosed near-equatorial trough extending around the globe. In austral summer, the thermally induced near-equatorial trough is centered to the south of the Equator, and thermal lows are found over the three southern

Figure 3 Mean patterns of 1000 mbar topography, with isoline spacing of 10 gpm in January and July. (Period 1958–97.)

continents. In boreal summer, the subtropical highs of both hemispheres and the enclosed near-equatorial trough appear displaced northward, and as part of this the monsoon heat low extends from northern hemispheric Africa to southern Asia. The domain of tropical circulation is meaningfully delineated by the subtropical high-pressure belts and anticyclonic axes of either hemisphere. From there the lower-tropospheric trade winds emanate to meet within a band of highest surface temperature and low-pressure trough near the Equator. The seasonality of heat-low processes is primarily responsible for the annual latitude migration of the equatorial trough.

Jet Streams

In the low latitudes various jet stream systems are developed at different times of the year. The upper-tropospheric Subtropical Westerly Jet is a feature of the respective winter hemisphere and owes its existence to the convergence of the poleward transport of absolute angular momentum in the upper and poleward portion of the Hadley cells, and to other factors. The likewise upper-tropospheric Tropical Easterly Jet, extending from South-East Asia over the Indian Ocean and Africa to the Atlantic, is confined to the height of the summer and is related to the thermal wind pattern associated with the then strongly heated subtropics and the cooler equatorial atmosphere. Through cross-circulations in the entrance and exit regions it exerts a control on the surface climate. The West African Mid-Tropospheric Easterly Jet is also limited to the boreal summer and related to the thermal wind pattern, in this instance associated with the hot desert air to the north and the cool monsoon air to the south of the Intertropical Discontinuity. The East African Low-Level Jet (or Findlater Jet) appears in boreal summer at about 1 km, extending with clockwise curvature from the Southern Indian Ocean across the Equator to the Arabian Sea. It has been called the 'backbone' of the south-west monsoon circulation. The Equatorial Mid-Tropospheric Easterly Jet, a recent discovery, is related to the tongue of cold surface waters in the equatorial Pacific.

Subtropical Highs and Trade Winds

The subtropical highs are the source of the trades and function as major centers of action for the tropical circulation. They are located farthest away from the Equator during the respective summer, but in both hemispheres they assume a westernmost position in boreal summer. The trades represent the lower-tropospheric portion of the Hadley cells. They pick up moisture (and to a lesser extent sensible heat) from the tropical oceans, accumulate it below the trade inversion, and carry it into the equatorial trough zone, where rainfall and latent heat release are concentrated. The trades thus serve an important role in global energetics. The trade inversion is lowest and best developed in the eastern equatorward sector of the subtropical highs, and rises and weakens both equatorward and toward the central and western part both of the Atlantic and the Pacific. Large-scale subsidence is the major factor in the origin and maintenance of the trade inversion. [Figure 4](#) illustrates the rise

Figure 4 Sketch illustrating the rise of the trade inversion, change from subsidence to ascending motion, and increasing convective activity, along the tradewind trajectory.

of the trade inversion, the decreasing subsidence, and the increasing convective activity, along the trade wind trajectory.

Equatorial Trough Zone

The equatorial trough zone and associated quasi-permanent circulation features are in their development and annual latitude migration controlled by heat-low mechanisms. Embedded within broad and coincident bands of high surface temperature and low pressure are an axis of confluence between airstreams of northern- and southern-hemispheric origin and a belt of maximum convergence–cloudiness–rainfall. The latter is typically located well away from the confluence axis, the separation being particularly large over northern-hemispheric Africa and the adjacent Atlantic. Thus insolation in the latitude of highest surface temperature and lowest pressure is ensured by comparatively scarce cloudiness. The meridional-vertical cross-section in [Figure 5](#) illustrates the structure of the equatorial trough zone in the West African–tropical Atlantic sector. In the season and longitudes of strong development and far northerly location of the flow discontinuity, the moist cross-equatorial flow from the southern hemisphere undercuts the Northeast trades in a wedge

Figure 5 Schematic meridional-vertical cross-section across the Equatorial Trough Zone in the tropical Atlantic–West African sector, showing 1000 mbar topography, maxima of surface temperature (TEMP MAX) and convergence (CONV MAX); meridional component of north-east tradewinds and of cross-equatorial flow from the Southern Hemisphere; Intertropical Divergence Zone (ITDZ), and Intertropical Convergence Zone (ITCZ), and flow confluence (Intertropical Discontinuity, ITD).

Figure 6 Zonal-vertical cross sections showing equatorial zonal circulation cells. Shading delimits the domains for which data were sampled, and horizontal lines mark the 200, 500 and 850 mb levels. Vertical arrows denote the omega vertical motion at 500 mb, and horizontal arrows horizontal divergent flow at 200 and 850 mb. Inset, upper right, explains the arrangement of arrows representing $5 \times 10^{-4} \text{ mb s}^{-1}$, and 5 m s^{-1} . (a) January, (b) April, (c) July, (d) October. Adapted from Hastenrath, S., 2007. Equatorial zonal circulations: historical perspectives. *Dynamics of Atmospheres and Oceans* 43, 16–24.

fashion. The dynamics of the cross-equatorial flow over the eastern Atlantic and Pacific are dominated by the latitude variation of the Coriolis parameter. Among the resulting characteristics are a recurvature of flow from south-easterly to south-westerly at about 5° N , a speed maximum at that latitude, a band of divergence between Equator and recurvature, the Intertropical Divergence Zone (ITDZ), and a band of convergence poleward from it, the Intertropical Convergence Zone (ITCZ). The Pacific Equatorial Dry Zone extending from the eastern to the central Pacific has ITDZ characteristics. Meridional climatic gradients from the Pacific Equatorial Dry Zone to the zonally oriented band of intense convergence–cloudiness–rainfall, the ITCZ, are among the steepest found on Earth in the absence of topographic effects. Over the Indian Ocean during the south-west monsoon the cross-equatorial flow recurves near the Equator, owing to a marked zonal component of the pressure gradient.

Monsoons

The monsoon area of the world is delineated primarily in terms of the complete annual reversal of wind regimes, thus encompassing the Indian Ocean sector and much of tropical Africa. Over sub-Saharan West Africa during boreal summer, a deep moist airstream from the southern hemisphere replaces and undercuts the dry Northeast trade winds originating from the Sahara. In the Indian Ocean sector during boreal winter, winds sweep from southern Asia across the Equator into the southern hemisphere. Of far greater proportions is the boreal summer Southwest monsoon. The establishment of a heat-low-induced monsoon trough over South Asia is instrumental in its development. In the South Indian Ocean Southeast trades

recurve, cross the Equator, and continue into the South Asian continent as the Southwest monsoon. Monsoon depressions and ‘breaks in monsoon’ are among the more important synoptic situations. On the Indian subcontinent and adjacent regions, the bulk of the annual precipitation falls during the Southwest monsoon. By contrast, the greater Indonesian region and parts of South-East Asia receive much of their annual rainfall during the boreal winter monsoon, with north-easterlies blowing over the South China Sea. More complicated regimes are found in equatorial East Africa, where the precipitation peaks are timed in the monsoon transition seasons. The bulk of the water vapor brought to condensation over South Asia during the boreal summer Southwest monsoon stems from south of the Equator. Atmosphere, hydrosphere, and lithosphere are all essential for the energetics of the monsoon.

Equatorial Zonal Circulations

The dynamics of zonal circulation cells in the near vicinity of the Equator are characterized by vanishing Coriolis acceleration, and thus balance between the pressure gradient and frictional accelerations. Pertinent are the coherence of vertical motion at the western and eastern extremities and the continuity of the divergent part of the zonal flow following the motion. **Figure 6** illustrates the existence of equatorial zonal circulation cells in the course of the annual cycle. A well-developed zonal circulation cell persists along the Pacific Equator all year round, the so-called ‘Walker circulation’, with ascending motion over the central Pacific, divergent to convergent eastward flow in the upper troposphere, subsidence over the eastern Pacific, and compensating divergent- to-convergent westward flow in the

realm of the Equatorial Mid-tropospheric Easterly Jet. Over the Indian Ocean, a distinct equatorial zonal circulation cell exists in boreal autumn only, with ascending motion over Indonesia, divergent-to-convergent westward flow in the upper troposphere, subsidence over the coast of East Africa, and compensating divergent-to-convergent eastward flow concentrated in the mid troposphere. In the Atlantic sector, a weak zonal cell is found in boreal winter, with ascending motion over the mouth of the Amazon, and upper-tropospheric eastward divergent outflow to a subsidence center over the eastern Atlantic.

Climatology of Weather Systems

Weather systems play an important role in the regional climate, and their occurrence is related to the large-scale circulation setting. In comparison with the higher latitudes there is a vast diversity of weather systems in the tropics. A few regionally important systems are considered here.

Most destructive are the Tropical Storms; systems beyond a certain intensity are called Hurricanes in the Americas, Typhoons in the Western Pacific, and Cyclones in the Indian Ocean. The major regions of storm formation are the western Atlantic and the Caribbean, the eastern Pacific, the eastern South Indian Ocean, the Arabian Sea and the Bay of Bengal.

Waves in the easterlies are the most common disturbances of the trade wind regime. Waves form with preference between about 15° E and 20° E to the south of the West African Mid-Tropospheric Easterly Jet. In boreal summer, a wave crosses the West coast of Africa about every 3–4 days. Passing on to the cold eastern Atlantic, the waves generally decay, but remnants survive to the western Atlantic and Caribbean, where some regenerate and account for about half of the Atlantic tropical Cyclones.

Squall Lines are among the more severe storms in the tropics. A system is typically hundreds of kilometers in meridional extent and consists of a line of active thunderstorms. These are particularly common over sub-Saharan Africa in boreal summer, but they have also been described from the western Atlantic, the equatorial central Pacific, and northern India. Over sub-Saharan West Africa they account for the bulk of the annual rainfall.

The Temporales of Pacific Central America originate as disturbances in the Intertropical Convergence Zone over the Eastern Tropical Pacific, especially during May–June and September–October. Temporales are feared for their abundant and sustained rainfall, and the hazards of landslides and flooding.

Wintertime cold-air intrusions from mid latitudes affect various regions of the global tropics, namely the Central American–Caribbean region, eastern South America, both northern- and southern-hemispheric Africa, and South-East Asia. Though of extratropical origin, they interact with tropical weather systems and play a distinct role in the regional climate.

Climatic Variability

The quasi-permanent regional circulation systems documented in a previous section undergo variations not only in the annual cycle but also from year to year and on longer time scales. A

direct consequence of such variability in the regional circulation is the variation in climate of tropical regions, with rainfall anomalies being of primary interest for the low latitudes. Much publicity has been given to the Southern Oscillation (SO), which has at its heart a pressure seesaw between the eastern and western extremities of the Pacific. To the extent that it is associated with changes in the quasi-permanent regional circulation systems, it may be reflected in regional rainfall anomalies; weak manifestations of the SO are indeed pervasive. Essential is the forcing by the regional circulation. Only a few regional themes are considered here.

Southern Oscillation and El Niño

The Southern Oscillation entails a large-scale pressure seesaw, on a time scale of 2–10 years, and with dipoles over the eastern South Pacific and the greater Indonesian-Australasian region, but spanning the global tropics. The low phase of the SO can be defined by anomalously low/high surface pressure at Tahiti/Darwin. Although these large-scale, long-term pressure variations have been studied since the latter part of the last century, their causal relation to the El Niño phenomenon on the West coast of South America has been recognized only since the 1970s.

During the high phase of the Southern Oscillation, both the eastern South Pacific high and the Indonesia low are strongly developed, and vigorous easterly trade winds sweep the equatorial Pacific, piling up waters at its western extremity. Accordingly, the eastward slope of the free ocean surface, the westward deepening of the oceanic mixed layer, and the Equatorial Undercurrent are pronounced, and waters are particularly cold off the South American West coast and in an extended zone immediately to the South of the Equator stretching from the coast of the Americas far into the open Pacific. Within the atmosphere, the Walker circulation along the Pacific Equator is strong, featuring not only vigorous surface easterlies but also an enhanced westerly return flow aloft, as well as pronounced convection and ascending motion over the Indonesian dipole and marked subsidence over the East Pacific dipole.

During the low phase of the Southern Oscillation, the atmosphere–ocean system in the Pacific operates in a remarkably different mode. Both the Eastern South Pacific high and the Indonesia low are weak; the slackened zonal pressure gradient entails weaker surface easterly winds in the equatorial zone, and accordingly the zonal slopes of the free ocean surface, of constant-pressure topographies at depth, and of the thermocline, diminish; the Equatorial Undercurrent slows down and may surface or vanish altogether. The relaxation of surface wind stress incites equatorial Kelvin waves which travel to the eastern extremity of the Pacific within 2–3 months, where they are manifest in a warming of surface waters, with maximum around the March–April peak in the annual march. The warm ocean and torrential rains at the otherwise deserts coast of Peru and Ecuador trigger an ecological catastrophe, including the mass death of fish and Guano birds, floods, destruction of roads and houses, and loss of human life. Within the atmosphere, the Walker circulation along the Pacific Equator is weak, as manifest in the slackened trade winds and westerly return flow aloft, as well as reduced convection,

rainfall, and ascending motion over the Indonesia dipole and lesser subsidence over the eastern Pacific.

Variations of the upper-air circulation are an essential part of the El Niño Southern Oscillation (ENSO) phenomenon. During the high or cold phase, the troposphere is anomalously cold throughout the global tropics, so that upper-tropospheric topographies are low, particularly in the lower latitudes, thus entailing departure easterlies and equatorward flow aloft. By contrast, during the low or warm phase, the tropical troposphere is warm, upper-tropospheric topographies are inflated – especially in the tropics – and departure westerlies and poleward flow prevail in the upper troposphere. These variations appear broadly in phase throughout the tropical belt, but the oceanic warming and cooling, and consequently the temperature variations in the overlying atmosphere, as well as the upper-tropospheric height variations, are most pronounced in the eastern to central Pacific. This allows for zonal flow departures in the upper troposphere over the equatorial zone of the Western Pacific to run essentially inverse to most of the remainder of the tropics. The aforementioned zonal flow variations in the upper troposphere over the equatorial western Pacific are an integral part of the modulations in the Walker circulation.

Indian Monsoon

Indian south-west summer monsoon rainfall is associated with characteristic circulation departure patterns from the pre-monsoon throughout the post-monsoon seasons. Abundant rainfall is heralded by strong heat low development over the continent, strong surface wind and a warm Arabian Sea preceding the monsoon onset. The negative correlation with pressure and the positive coupling with wind persist to the post-monsoon season. Enhanced upper-tropospheric easterlies throughout the summer half-year are further indicative of a good monsoon year. Abundant rainfall years tend to coincide with the high or cold phase of the Southern Oscillation.

Northeast Brazil

The droughts of northern Northeast Brazil (the Nordeste), which has its rainy season concentrated mainly in March–April, are characterized by an anomalously far poleward position of the near-equatorial trough and embedded confluence axis and convergence band; positive sea surface temperature departures in the tropical North Atlantic; and anomalously cold waters in the equatorial South Atlantic. Surface circulation features conducive to drought include the distant position of the convergence band; the cold south equatorial water and its resulting effects on moisture and instability of the boundary layer flow; and enhanced meridional temperature contrasts across the Equator, which drive a thermally direct meridional circulation cell in the atmosphere, featuring subsidence over the Nordeste. Departure patterns in the large-scale atmospheric and ocean fields are approximately inverse in the dry and wet years, and evolve during the half-year preceding the Nordeste rainy season, thus offering the prospect of climate prediction.

Sahel

Droughts in sub-Saharan Africa, which experiences its rainfall at the height of the boreal summer, are associated with an anomalously far equatorward position of quasi-permanent circulation features, in particular the surface confluence axis and convergence band, and negative sea surface temperature anomalies are found in a broad band across the tropical North Atlantic. Anomalously warm surface waters in the western Indian Ocean and in the equatorial Pacific also tend to be associated with deficient Sahel rainfall.

In addition to the interannual variability, the Sahel zone of West Africa has experienced since the middle of the past century a trend towards much drier conditions, in tune with the long-term evolution of the large-scale circulation setting. This is in part illustrated in Figure 7. Given the steep meridional gradient of annual rainfall totals from the Sahara desert to the coast of the Gulf of Guinea, the drastic downward trend of Sahel rainfall is commensurate with the observed southward displacement of the wind confluence over the adjacent Atlantic. A further characteristic of the evolution from the middle of the century to the mid 1980s was a cooling of the tropical North Atlantic. Since the mid 1980s there have been tenuous indications for a recovery from the prolonged drought regime, along with a northward shift of the wind confluence and the warming of the tropical North Atlantic waters. The long-term trend in Sahel rainfall must be seen in the context of an evolving general circulation, rather than as a mere response to the local alterations of surface conditions.

Time Scales of Variability

Interannual variability appears concentrated in various preferred time scales. A quasi-biennial oscillation is apparent in India's rainfall, in the circulation over the equatorial Atlantic and in rainfall over Northeast Brazil, as well as in other elements and areas. Northeast Brazilian rainfall and the equatorial Atlantic circulation further exhibit spectral power at around 13–14 years. By contrast, interannual variability in various regions of the outer tropics and subtropics of the Americas and Africa (Central American–Caribbean area, sub-Saharan Africa, Southern Africa, subtropical South America) is concentrated at a time scale of 2–3 decades. Positive-feedback mechanisms may play a role in the persistence of anomalous regimes in these semi-arid to semi-humid regions. The coexistence of various preferred time scales of interannual variability in the Atlantic and surrounding continents is re-markable.

Climate Prediction

Climate anomalies such as those discussed in the preceding sections can have a severe social and economic impact. Accordingly, it has long been found desirable to find ways of predicting such events well in advance. While the hazards posed by certain tropical weather systems, in particular the Tropical Storms and Squall Lines, are recognized, in the tropics seasonal forecasting has arguably even greater practical relevance than weather forecasting. The diagnostic understanding

Figure 7 Long-term evolution of circulation and climate in the West African–Atlantic sector (a) Sahel rainfall; (b) latitude of wind confluence (zero meridional wind component) over the tropical Atlantic. Adapted from Hastenrath, S., 1995. *Climate Dynamics of the Tropics*. Kluwer, Dordrecht, Boston, London.

of circulation and climate variability is essential for the development of climate prediction methods. Empirical as well as numerical modeling approaches are being used to that end. There are prospects of success for certain tropical regions.

Introduction

The term Walker Circulation was first introduced in 1969 by Professor Jacob Bjerknes, referring to the large-scale atmospheric circulation along the longitude–height plane over the equatorial Pacific Ocean. The Walker Circulation features low-level winds blowing from east to west across the central Pacific, rising motion over the warm water of the western Pacific, returning flow from west to east in the upper troposphere, and sinking motion over the cold water of the eastern Pacific. Since Bjerknes's introduction of the Walker Circulation, there have been reports of similar east–west circulation cells spanning different longitudinal sectors along the Equator. Today, the Walker Circulation generally refers to the totality of the circulation cells as shown in Figure 1.

Bjerknes originally named the Pacific east–west circulation the Walker Circulation because he considered it the key part of Sir Gilbert Walker's Southern Oscillation (*see Tropical Meteorology and Climate: El Niño and the Southern Oscillation: Observation*). He interpreted the Walker Circulation as an atmospheric circulation driven by the gradient of sea surface temperature along the Equator and suggested that the characteristics of the Walker Circulation were largely determined by the coupling between the tropical atmosphere and oceans.

Bjerknes's work on the Walker Circulation marked an important milestone toward our basic understanding of the dynamics of zonal atmosphere–ocean coupling along the equatorial Pacific Ocean. Although his results were based on very limited data, Bjerknes's original conjecture that the year-to-year variation of the Walker Circulation is closely tied to that of the Southern Oscillation and El Niño has been confirmed by a large number of observational and modeling studies during the several decades since his first report.

Climatology and Variability

Annual Mean

Thanks to the advance in satellite observations and improved assimilation of observations into global general circulation models, now a much more detailed and quantitative description of the Walker Circulation is available. It is known that the tropical wind is made up of rotational and divergent components. The former is directly related to the effects of the rotation of the Earth and the latter to the overturning circulation, driven by atmospheric heating processes. The Walker Circulation and associated overturnings in the equatorial plane should refer only to the divergent component of the wind. Figure 2(a) shows the annual climatology (the mean state of all months) of the overturning circulations along the equatorial plane as streamlines constructed from the divergent zonal and vertical winds. It can be seen that the major rising branch of the Walker Circulation is found over the western Pacific and maritime continent, with a maximum in the upper troposphere (300–200 hPa) over Indonesia (115–120° E). A westward tilt with height of the ascending motion is also apparent. Over the eastern Pacific, there is a broad region of subsidence, with maximum descent in the coastal region of South America (~80° W). Connecting the ascending and descending branches are low-level easterlies and upper level westerlies over the central and eastern Pacific with strong low-level convergence near 160° E.

As is evident in Figure 2(a), the Walker Circulation also includes secondary circulation cells whose rising motions appear over the land regions of South American and Africa, with compensating subsidence over the Atlantic and the Indian Ocean. Compared with the Pacific branch of the Walker Circulation, these cells cover smaller longitude ranges and tend to have weaker vertical motions in the annual mean climatology.

Figure 1 Schematic view of the east–west atmospheric circulation along the longitude–height plane over the Equator. The cell over the Pacific Ocean is referred to as the Walker Circulation. Adapted from Webster, P.J., 1983. The large scale structure of the tropical atmosphere. In: Hoskins, B.J., Pearce, R.P., (Eds.), *General Circulation of the Atmosphere*. Academic Press, London, UK, pp. 235–275.

Figure 2 The equatorial east–west atmospheric circulation calculated from the reanalysis of data from the US National Centers for Environmental Prediction and National Center for Atmospheric Research. Shown are the climatologies of all months (top panel), January (middle panel), and July (bottom panel) for the period 1949–99. The streamlines are constructed from the divergent components of the winds (meters per second), with the values of the vertical motions multiplied by 30 times. Areas of strong upward (positive values) and downward motions (negative values) are colored.

Also closely linked to the Walker Circulation are the east–west circulations away from the equatorial region in the subtropics, associated with the large-scale monsoon circulation and the convergence of the trade winds. Some meteorologists consider these circulations part of the family of Walker cells.

Because of the prevailing subsidence, the atmosphere over the tropical eastern Pacific is highly stable. This stability is unfavorable to and limits the occurrence of deep clouds and precipitation. In contrast, over the warm pool (see

Oceanographic Topics: General Processes) of the western Pacific and Indonesian region, the air is unstable and deep convective clouds and heavy precipitation occur frequently. A significant portion of latent heat associated with cumulus convection (see **Thermodynamics: Moist (Unsaturated) Air**) that drives the global atmospheric circulation is released in the ascending region of the Walker Circulation over the warm pool. In addition, the Walker Circulation is associated with low sea level pressure in the west and high pressure in the east. The

basin-wide pressure gradient is the main driving force for the low-level zonal wind of the Walker Circulation. Consistent with the distribution of surface pressure and sea surface temperature, the lower troposphere is relatively warm in the ascending branch and cold in its descending branch. This means that the Walker Circulation is a thermally direct circulation, which converts available potential energy to kinetic energy of atmospheric motions.

Seasonal Variations

The location and intensity of the Walker Circulation undergo large fluctuations on seasonal to interannual timescales. Also affecting the Walker Circulation are intraseasonal fluctuations associated with the Madden and Julian Oscillation (see **Tropical Meteorology and Climate: Intraseasonal Oscillation (Madden–Julian Oscillation)**). The seasonal variation of the Walker Circulation is a reflection of the east–west swaying of the large-scale circulation in the tropical atmosphere in response to thermal contrasts between sea and land induced by the annual cycle of incoming solar radiation. In January (**Figure 2(b)**), the ascending branch of the Walker Circulation is very pronounced over the Indo-Pacific and maritime continent region ($60\text{--}120^\circ\text{ E}$) and the descending branch over the eastern Pacific ($150\text{--}90^\circ\text{ W}$). The South America–Atlantic cell is strong, with pronounced rising motion over the northeastern Brazil ($\sim 60^\circ\text{ W}$). However, the Africa–Indian Ocean cell is not very well established in January. In July (**Figure 2(c)**), the Walker Circulation intensifies and becomes well-defined, with the rising branch shifted eastward and concentrated near 150° E and the sinking branch over the eastern Pacific ($120\text{--}90^\circ\text{ W}$). The strengthening of the Walker Circulation is consistent with the seasonal development of the cold water over the equatorial eastern Pacific and the increased sea surface temperature gradient across the Pacific. Mid-tropospheric sinking motion is found over the eastern Indian Ocean. This sinking motion is connected by low-level westerly wind blowing from the Indian Ocean toward the western Pacific, joining the rising motion there. The overturning is completed by the returning upper level easterlies over the Indian Ocean. The Indian Ocean cell is associated with the development of the South Asian monsoon (see **Tropical Meteorology and Climate: Monsoon: Overview**). In July, the overturning motion over the South America–Atlantic sector is suppressed.

Interannual Variability

Figure 3(a) shows the Walker Circulation during January 1998 when an El Niño event was at its peak. Here, the east–west circulations comprising the Walker Circulation differed significantly from the climatology. Rising motions prevailed at almost all longitudes. In particular, strong ascent in the mid-troposphere replaced climatological descending motion over the central and eastern Pacific, where the water was anomalously warm due to El Niño. The Walker Circulation was weakened and became less organized. On the contrary, during January 1999 when a La Niña, or reverse El Niño, was at its peak, the Walker Circulation was enhanced and became very pronounced, with well-defined rising and sinking branches

(**Figure 3(b)**). While the Walker Circulation and South America–Atlantic cell intensified, the Indian Ocean cell weakened compared to the climatology (see **Tropical Meteorology and Climate: Monsoon: ENSO–Monsoon Interactions**). Changes in the Walker Circulation between El Niño and La Niña years shown above are accompanied by changes in cloud and rainfall patterns. In contrast, when the Walker Circulation weakens during an El Niño, clouds and precipitation increase over the central–eastern Pacific and decrease over the western Pacific. In contrast, when the Walker Circulation strengthens during a La Niña, clouds and precipitation are enhanced over the western Pacific and Indonesian region.

Ocean–Atmosphere Coupling

As Bjerknes postulated, the Walker Circulation and its variations are strongly coupled to fluctuations of the tropical sea surface temperature across the entire Pacific basin. A climatological Walker Circulation with strong surface easterlies maintains an equilibrium state in the tropical atmosphere and ocean in which the western Pacific is characterized by higher sea level, deeper thermocline, higher sea surface temperature, lower atmospheric surface pressure, and increased precipitation relative to the eastern Pacific. During an El Niño, a relaxation of the lower level easterlies, signaling a weakening of the Walker Circulation, is accompanied by weaker upwelling in the eastern Pacific, leveling of the thermocline, and reduction of sea surface temperature gradient across the Pacific. During a La Niña, changes of the opposite sign occur.

The apparently self-sustaining oscillations of the Walker Circulation stem from the interplay of various feedback processes associated with strong coupling of the tropical atmosphere and oceans. Warming of the western Pacific increases the convective potential energy of the atmosphere, resulting in deep convection and heavy precipitation. However, the more abundant cloud amounts associated with increased precipitation reduce the incoming solar radiation, causing the sea surface to cool, thus limiting the further development of atmospheric convection. This process tends to slow down the Walker Circulation and arrest the warming. On the other hand, the warm sea surface temperature and strong upward atmospheric motions will lead to stronger surface easterlies that induce further warm water in the western Pacific and cool water in the eastern Pacific through increased upwelling. The increased east–west sea surface temperature gradient can lead to a stronger Walker Circulation. The aforementioned process was interpreted by Bjerknes as an acceleration of the Walker Circulation that also provides for ‘an increase of the east–west temperature contrast that is the cause of the Walker Circulation in the first place’.

Impacts on World Weather and Climate

The Walker Circulation regulates global exchange of momentum, heat, and water vapor within the tropics via massive overturning motions. In doing so, it plays an important role in the balance of atmospheric energy in the equatorial region and in determining the characteristics of

Figure 3 The equatorial east–west atmospheric circulation, calculated from the reanalysis of data from the US National Centers for Environmental Prediction and National Center for Atmospheric Research, for January 1998 (peak of an El Niño; panel (a)) and January 1999 (peak of a La Niña; panel (b)). The streamlines are constructed from the divergent components of the winds (meters per second), with the values of the vertical motions multiplied by 30 times. Areas of strong upward (positive values) and downward motions (negative values) are colored.

weather and climate in the tropics. The strongest atmospheric impacts associated with the fluctuations of the Walker Circulation are found over tropical and subtropical regions around the Pacific rim. During an El Niño, the weakening Walker Circulation causes widespread drought (*see Hydrology, Floods and Droughts: Drought*) in Indonesia-maritime continent, drought in northeastern Brazil, severe floods (*see Hydrology, Floods and Droughts: Flooding*) in Peru and Ecuador, and in southeastern Brazil and northern Argentina. During a La Niña, the Walker Circulation intensifies and leads to rainfall anomalies with reverse sign compared to El Niño. The Walker Circulation also represents

the fundamental link between the changes in sea surface temperature in the eastern Pacific and the variability of the Asian–Australian monsoon. The mechanisms that are responsible for the interactions between the monsoon and El Niño Southern Oscillation have been attributed, in part, to the changes in the Walker Circulation. Although individual cases may vary, in the summer preceding the peak phase of El Niño, which usually occurs in the northern winter, the Walker Circulation is weakened and shifted eastward owing to reduced east–west sea surface temperature gradient across the Pacific ocean. This suppresses broad-scale convection over the western Pacific and eastern Indian Ocean and leads to weaker

South Asian monsoon. There is some evidence that changes in land use, such as deforestation in Brazil and Indonesia, may also cause long-term changes in the Walker Circulation due to changes in land temperature, and therefore east–west thermal gradient along the tropical belt.

Besides modulating tropical weather and climate, the Walker Circulation is important as a driver of energy exchange between the tropics and higher latitudes. Bjerknes envisioned an interaction between the Walker Circulation and the Hadley Circulation in the form of an inverse variation between the two circulations. Bjerknes stated that “when the cold water belt along the Equator is well developed, the air above it will be too cold and heavy to join the ascending motion in the Hadley circulations. Instead, the equatorial air flows westward between the Hadley circulations of the two hemispheres to the warm west Pacific”. Such an interaction leads to changes in extra-tropical westerly jet streams (*see* **Synoptic Meteorology: Jet Streaks**) and the so-called Pacific–North American and Pacific–South American teleconnection patterns. These changes are the causes for severe weather and climate anomalies in the Asian–Pacific–American regions.

Summary

The Walker Circulation comprises east–west atmospheric circulation cells along the equatorial belt. The most dominant component is the Pacific branch, which consists of easterly winds at the lower troposphere, westerly winds at the upper troposphere, rising motion over the western Pacific, and subsidence over the eastern Pacific. The Walker Circulation possesses pronounced variability on seasonal intraseasonal and interannual timescales, and is an integral component of the El Niño–Southern Oscillation climate system. Fluctuations of the Walker Circulation can lead to extreme weather conditions in different parts of the world.

Synopsis

Particles are ubiquitous in the atmosphere. The tropospheric aerosol is remarkably diverse in its composition, reflecting the wide range of particle sources in the atmosphere. Chemical components of tropospheric particles include inorganic materials such as sulfate, ammonium, nitrate, trace metals, and a wide array of carbonaceous compounds. Concentrations of airborne particles vary greatly over the globe, from the lowest concentrations in pristine areas to the highest levels in polluted urban centers. Atmospheric aerosols carry the chemical signature of the sources of direct particle emissions into the atmosphere as well as that of the conversion of gaseous molecules into particulate-phase species.

Introduction

Atmospheric particles (aerosols) range in size from a few nanometers to tens of micrometers in diameter. (An aerosol is strictly defined as a suspension of fine liquid or solid particles in a gas. In common usage, however, the particles themselves are referred to as the aerosol.) Primary aerosols are those particles emitted directly into the atmosphere. Particles or particulate materials are also formed in the atmosphere by nucleation or condensation of vapor species; such gas-to-particle conversion processes are an important source of atmospheric particulate material.

Particles are ubiquitous in the atmosphere; there is no region of it totally devoid of them. Particles are, in fact, the nuclei for the formation of clouds. Those particles that, in the presence of small amounts of water supersaturation, grow spontaneously to form cloud droplets are called cloud

condensation nuclei (CCN). The number of particles in a given ambient population that will form cloud droplets in a certain situation depends on the amount of ambient water supersaturation and the composition of the particles themselves. Particles containing water-soluble compounds preferentially act as CCN over those that contain largely insoluble compounds.

The troposphere is the lowest layer of the atmosphere, ranging from the Earth's surface to an altitude of about 10–15 km, depending on latitude and time of year. The temperature in the troposphere decreases with altitude – this leads to a dynamically unstable situation where mixing from the surface up to the top of the troposphere occurs on the order of a week or so. All of the atmosphere's weather and most of its water are in the troposphere. The atmospheric layer lying on top of the troposphere is the stratosphere, extending to an altitude of about 50 km. The temperature in the

stratosphere increases with altitude, leading to a dynamically stable layer in which vertical mixing processes are slow. The coldest point in the atmosphere between the surface of the Earth and the top of the stratosphere is at the troposphere–stratosphere boundary, the tropopause. Typical tropopause temperatures are about 220 K. When tropospheric air penetrates up into the stratosphere, water vapor in that air is frozen out at the tropopause; consequently, the stratosphere is very dry and generally cloudless. (Stratospheric clouds do form at the extremely cold temperatures of the winter stratosphere over the poles, where even the small amount of water vapor is frozen to form polar stratospheric clouds.)

Particles are eventually removed from the atmosphere by two routes: deposition at the Earth's surface ('dry' deposition) and incorporation into cloud droplets, either as the droplets form or as they fall ('wet' deposition). Because the troposphere is fairly vigorously mixed and because the incidence of precipitation is frequent, the lifetime of particles in the troposphere is relatively short, ranging from a few days to a few weeks. (Because the only route for the removal of stratospheric aerosols from the atmosphere is relatively slow transport down into the troposphere, where they are subject to removal by wet or dry deposition, stratospheric particles can have lifetimes of several years.) While not all particles released simultaneously into the atmosphere will remain in the atmosphere for an identical amount of time, there is an average residence time, or lifetime, for such particles. For a well-mixed atmospheric reservoir, the mean residence time of particles is the total mass of particles in the reservoir divided by their overall rate of removal, expressed in mass per time. Since there is a highly nonuniform geophysical distribution of particle sources over the globe, the relatively short residence time of particles leads to a highly nonuniform distribution of aerosols in the troposphere; that is, particles are simply not airborne long enough to become uniformly mixed throughout the troposphere. As a result, tropospheric aerosols tend to be categorized according

to the different areas of the Earth in which they are found, such as marine, desert, urban, rural, etc.

Chemical Components of Atmospheric Aerosols

This article addresses the composition of airborne particles in the troposphere. The tropospheric aerosol is remarkably diverse in its composition, reflecting the wide range of particle sources at the Earth's surface. Figure 1 depicts schematically the chemical components of tropospheric particles and their routes of incorporation into the aerosol phase. Chemical components of tropospheric aerosols include inorganic materials such as sulfate, ammonium, nitrate, sodium, chloride, trace metals, crustal elements, carbonaceous material, and water. Particles in different regions of the troposphere contain these species in differing amounts and proportions, but most of the mass of airborne tropospheric particles is represented by the collection of species depicted in Figure 1. In the remainder of this article, we discuss the sources of each of these classes of species, and how their absolute amounts vary in different regions of the troposphere.

Some aerosol constituents are relatively inert and nonvolatile, and their presence in the particulate phase does not depend on the composition of the atmosphere in which the particles are dispersed. Examples of such components are metals, like lead, and alkaline Earth elements, such as calcium and magnesium. The elemental composition of such materials in aerosols can be related directly to the sources of particles emitted into the atmosphere. Other aerosol species are more volatile, such that they are distributed between gaseous and aerosol (aqueous or solid) phases in the atmosphere, and this phase distribution depends on atmospheric conditions. Atmospheric acids and bases fall into this category, as do carbonaceous compounds with vapor pressures sufficiently low for the species to distribute themselves

Figure 1 Chemical components of tropospheric aerosols and their routes of incorporation into the aerosol phase. EC, elemental carbon; OC, organic carbon.

between the gas and aerosol phases but not so low that the compounds lie entirely in the particulate phase. Compounds with vapor pressures in the range where they are distributed between the gas and aerosol phases are often referred to as semivolatile.

Inorganic Aerosols

Sulfur is a ubiquitous component of atmospheric aerosols. Whereas some particles are directly emitted, containing sulfur, the majority of the sulfur in atmospheric aerosols is the result of gas-to-particle conversion. The principal gaseous atmospheric precursor to aerosol sulfur is sulfuric acid (H_2SO_4), which is produced in the atmosphere from the oxidation of sulfur dioxide (SO_2). Sulfur dioxide has both natural and anthropogenic sources. The most important anthropogenic source of SO_2 is combustion of sulfur-containing fuels. A major natural source of SO_2 is the atmospheric oxidation of dimethyl sulfide (CH_3SCH_3) emitted from oceanic phytoplankton. Gaseous sulfur dioxide reacts with the hydroxyl (OH) radical through a series of steps to produce the H_2SO_4 vapor molecule. Sulfuric acid has an extremely low vapor pressure; consequently, it rapidly condenses on any available particles. In some instances, when sufficient aerosol surface area is not present to absorb the sulfuric acid, H_2SO_4 , in combination with water molecules, will spontaneously nucleate to form new ultrasmall particles. Sulfates have vapor pressures low enough for them to tend, when present, to reside overwhelmingly in the aerosol phase.

In addition to sulfuric acid, NH_3 , HNO_3 , and HCl are the major inorganic vapors involved in formation and growth of atmospheric aerosol. A principal source of chlorine in the atmosphere is sea salt particles. The NaCl in sea salt can react with sulfuric and nitric acids to produce gaseous HCl :

Gas-phase ammonia can react with acid vapors to form ammonium salts in the aerosol phase. Products include NH_4NO_3 , $(\text{NH}_4)_2\text{SO}_4$, NH_4HSO_4 , and NH_4Cl . The reversible reaction

is the principal source of nitrate in atmospheric aerosols. An analogous reaction is the equilibrium among NH_3 , HCl , and NH_4Cl :

When the relative humidity is sufficiently high, the particle phase becomes an aqueous solution, and the above salts dissociate into their corresponding ions: NH_4^+ , NO_3^- , H^+ , Na^+ , Cl^- , HSO_4^- , and SO_4^{2-} . These ions play an important role in governing the amount of liquid water in the aerosol particle at a given ambient relative humidity.

Deliquescence Behavior of Atmospheric Aerosols

With a single aqueous phase containing dissolved electrolytes, when compounds condense or evaporate, water must also

condense or evaporate to maintain the particle water activity equal to the ambient relative humidity. Thus, the water content of particles changes in response to condensation or evaporation of electrolytes, or in response to changes in ambient relative humidity itself (Figure 2). At a fixed electrolyte content, as the ambient relative humidity is lowered, water evaporates from the particle to maintain equilibrium. If the relative humidity is lowered sufficiently, a solid crystalline phase may form when one or more of the electrolytes reach saturation. For instance, if the particle contains sodium chloride, this solid phase will occur theoretically at 75% relative humidity. This defines the efflorescence point, which, according to equilibrium thermodynamics, is equivalent to the deliquescence point – the efflorescence point defines the relative humidity where the aqueous-to-crystalline phase transition occurs, whereas the deliquescence point defines that of the crystalline-to-aqueous transition. In general, the deliquescence point is a function of temperature, and this dependence can be derived from the Clausius–Clapeyron equation. The efflorescence and deliquescence points generally do not coincide, because nucleation of the new crystalline phase typically does not occur until the solution is substantially supersaturated (Figure 2).

For single-salt solutions, there is a single deliquescence point separating the higher relative humidities (where the particle is aqueous) from the lower relative humidities (where the particle is crystalline). Aqueous particles containing, for instance, sulfuric acid do not display a deliquescence point, because no solid phase of sulfuric acid exists for typical tropospheric temperature ranges.

If the particle contains multiple salts, or combinations of salts and acids, there is a range of relative humidities where aqueous and solid phases can coexist in equilibrium. Consider, for example, two salts in solution. As the relative humidity is lowered, eventually one of the salts becomes saturated and forms its crystalline phase. As the relative humidity continues

Figure 2 Deliquescence and crystallization behavior of atmospheric aerosols. Growth (filled circles) of an initially dry ammonium sulfate (namely, $(\text{NH}_4)_2\text{SO}_4$) particle as relative humidity (RH) is increased. The particle remains dry until about 80% RH, where it spontaneously takes on water (deliquesces). Subsequently, as the wet particle is exposed to decreasing RH (open circles), the particle remains wet below 80% RH and finally crystallizes at around 30% RH. This hysteresis behavior upon wetting and drying is typical of atmospheric inorganic salts.

to decrease, more of this salt precipitates, and the solution becomes simultaneously more concentrated in the non-precipitating salt. Eventually, the nonprecipitating salt reaches its saturation, and further decreases in relative humidity cause the particle to effloresce completely. If the particle contains a salt and an acid, the first deliquescence will occur, but the aqueous phase will continue to persist, owing to the absence of a deliquescence point for the acid. It can be shown that the deliquescence points of nonreacting mixtures are always lower than those of the single solutes.

Carbonaceous Aerosols

Carbonaceous material is a ubiquitous component of atmospheric aerosols. From combustion processes, carbon-containing compounds are emitted directly into the atmosphere in particulate form, a prime example of which is soot. In addition, during the gas-phase atmospheric oxidation of organic gases (by species such as OH, O₃, and NO₃), products are formed with oxygen-containing functional groups. These products tend to have lower vapor pressures than their parent organic molecules, and, as a result, can condense to the aerosol phase. Carbonaceous material incorporated into particles by this route is referred to as secondary organic aerosol. Natural hydrocarbons like the monoterpenes (a class of compounds having the chemical formula C₁₀H₁₆) lead to secondary organic aerosol when oxidized in the atmosphere by OH, O₃, and NO₃. In areas of high vegetation coverage, terpenes can contribute a substantial amount of organic aerosol.

The carbonaceous fraction of atmospheric aerosol is often divided according to elemental carbon (EC) and organic carbon (OC). Loosely speaking, EC refers to that fraction of the aerosol collected on a filter that cannot be vaporized upon heating. Chemically, EC is associated with sootlike compounds. By contrast, OC represents that fraction of the carbon-containing material that can be vaporized. Thus, the division of the carbonaceous material into EC and OC is essentially an operational one, defined on the basis of the technique used in measurement.

Degree of Chemical Mixing in Atmospheric Particles

All atmospheric particles of the same size do not have the same chemical composition. An 'externally mixed' aerosol population is defined as one in which different particles of the same size have different chemical compositions. In the extreme, an external mixture would consist only of particles containing individual pure substances, such as pure ammonium sulfate in one class of particles and pure EC in another class. Such complete segregation of substances does not occur. Rather, atmospheric aerosols consist of particles that initially have the chemical signature of their sources but, as they age in the atmosphere, take on other species from the gas phase or, possibly, coagulate with other particles.

Gas–Aerosol Equilibrium

The key thermodynamic properties of organic compounds that control their partitioning to condensed phases in the

atmosphere are the Henry's law constant (K_H), pure species vapor pressure (p^0), and, for substances that dissociate into ions in aqueous solutions, the dissociation constant (K_a). The atmospheric relative humidity and presence of other dissolved species in liquid aerosols also affect partitioning via the amount of condensed-phase water and the activity coefficient of the dissolved organic substance (in an aqueous or organic liquid phase). These relationships are briefly summarized here.

The solubility of an organic gas A in water is described by:

$$K_H = \frac{\gamma_A m_A}{p_A} \quad [1]$$

where K_H (mol kg⁻¹ atm⁻¹) is the Henry's law constant, m_A is the molality of A (moles of A per kilogram of liquid water), and p_A (atm) is the gas-phase partial pressure of A. The quantity γ_A is the activity coefficient of A in the aqueous phase and in an infinitely dilute aqueous solution has a value of unity. Aerosols can contain a large number of both inorganic and organic dissolved components, and γ_A is a function of the solution phase composition and the ambient relative humidity, which controls the concentrations of the dissolved components in the aqueous aerosol.

If the organic compound, for example, an organic acid RCOOH, dissociates significantly in aqueous solution,

then overall partitioning to the aerosol phase is enhanced, as the total molality of RCOOH in the aerosol phase is given by

$$m_{TOTAL} = m_{RCOOH} + m_{RCOO^-} \quad [2]$$

$$m_{TOTAL} = p_{RCOOH} K_H \left(\frac{1}{\gamma_{RCOOH}} + \frac{K_a}{m_H + \gamma_H \gamma_{RCOO}} \right) \quad [3]$$

where K_a (mol kg⁻¹) is the dissociation constant of the acid. It is apparent from eqn [3] that, in this case, partitioning is dependent upon the two equilibrium constants, aerosol pH (the hydrogen ion activity $m_{H^+} \gamma_H$) and the activity coefficients, γ_{RCOOH} and γ_{RCOO^-} .

Atmospheric condensed phases (clouds, fogs, aerosols) contain up to about 0.1 g water m⁻³ of atmosphere. It can be shown that, for an atmospheric gas to partition significantly into cloud water, the Henry's law constant (an 'effective' value, including the effects of any dissociation) must exceed 10⁴ mol kg⁻¹ atm⁻¹. This value is even greater if partitioning into aqueous aerosols (10⁻⁴–10⁻⁵ g water m⁻³) is considered.

Atmospheric Concentrations of Aerosols

The global tropospheric aerosol can be considered to consist of about five general categories of material: (1) sea salt; (2) soil dust; (3) inorganic salts (sulfate, nitrate, ammonium); (4) OC; and (5) EC. The relative proportions of each of these five classes vary over the globe. By sheer mass, sea salt has the largest flux into the atmosphere of any of the five categories, but the actual

mass of sea salt aerosol in the atmosphere at any time is actually less than that of soil dust. This is because sea salt aerosol does not rise vertically into the atmosphere very far above the ocean surface and falls back into the sea fairly readily. Soil dust, which has an estimated global emission rate about one-fifth that of sea salt, is actually estimated to have about twice the total mass loading in the atmosphere. This larger mass loading is a result of the fact that soil dust gets transported much higher in the atmosphere than sea salt and consequently has a much longer residence time in the atmosphere. Saharan dust is regularly measured in the air of Miami, Florida, for example. Inorganic salts, OC, and EC have principally anthropogenic sources, and these sources tend to be concentrated in the Northern Hemisphere. The average atmospheric residence time of these 'pollution' particles is on the order of a week. Given typical wind speeds, this means that such aerosols will tend to be located over and downwind of the heavily industrialized regions of the Northern Hemisphere. One exception to the overwhelming concentration of anthropogenic aerosols in the Northern Hemisphere is the carbonaceous aerosols emitted from burning of biomass, which occurs on a large scale in the Southern Hemisphere.

Concentrations of atmospheric aerosol components are usually reported in either of two ways. The first is the mass concentration, expressed in terms of micrograms of aerosol species per cubic meter of air, $\mu\text{g m}^{-3}$. The second is based on

the mole fraction of the species in air. A commonly used measure of the level of gaseous species in the atmosphere is mole fraction. For the trace atmospheric gases, important in atmospheric chemistry, mole fractions range from about 10^{-6} to 10^{-12} . These mole fractions are equivalent to the volume of species per volume of air. It has proved convenient to report such mole, or volume, fractions in terms of so-called mixing ratios, such as parts per billion (1 ppb: one part in 10^9 parts of air) or parts per trillion (1 ppt: one part in 10^{12} parts of air). Aerosol species concentrations can, likewise, be expressed in such mixing ratio units.

Figure 3 shows a distribution of aerosol chemical composition at many sites around the world, mainly in the Northern Hemisphere. These data were obtained with the Aerodyne Aerosol Mass Spectrometer. Aerosol composition is apportioned according to: sulfate, nitrate, ammonium, and organic compounds. A pie chart of composition is given for each site, and the mass concentration value below each pie chart is the annual average total mass concentration for that site. (The mass of water in the aerosol is not indicated, as water is evaporated from the particles in the course of measurement by the mass spectrometer.) Sites range from those in remote areas to those in major urban centers. The total aerosol mass concentration ratio between the most polluted cities and the most remote areas is as large as 70. Carbonaceous species (organics) constitute roughly one-half of the airborne particulate mass

Figure 3 Aerodyne Aerosol Mass Spectrometer datasets of global aerosol chemical composition. Colors for the study labels indicate the type of sampling location: urban areas (blue), <150 km downwind of major cities (black), rural/remote areas >150 km downwind (pink). Pie charts show the average mass concentration and chemical composition: organics (green), sulfate (red), nitrate (blue), ammonium (orange), and chloride (purple) of nonrefractory particles of diameter less than $1 \mu\text{m}$. Adapted from Zhang, Q., Jimenez, J.L., Canagaratna, M.R., Allan, J.D., Coe, H., Ulbrich, I., Alfarra, M.R., Takami, A., Middlebrook, A.M., Sun, Y.L., Dzepina, K., Dunlea, E., Docherty, K., DeCarlo, P.F., Salcedo, D., Onasch, T., Jayne, J.T., Miyoshi, T., Shimojo, A., Hatakeyama, S., Takegawa, N., Kondo, Y., Schneider, J., Drewnick, F., Borrmann, S., Weimer, S., Demerjian, K., Williams, P., Bower, K., Bahreini, R., Cottrell, L., Griffin, R.J., Rautiainen, J., Sun, J.Y., Zhang, Y.M., Worsnop, D.R., 2007. Ubiquity and dominance of oxygenated species in organic aerosols in anthropogenically influenced Northern Hemisphere midlatitudes. *Geophysical Research Letters* 34, L13801. <http://dx.doi.org/10.1029/2007GL029979>.

worldwide. As depicted schematically in Figure 1, carbonaceous species are both emitted directly in the particle phase as well as transferred from the gas phase to the aerosol phase in the atmosphere itself as a result of gas-phase chemical reactions that generate less volatile species.

Organic aerosol comprises a major fraction (18–70%; average = 45%) of the nonrefractory submicron particle mass at 37 global locations (Figure 3), while sulfate (10–67%; average = 32%), nitrate (1.2–28%; average = 10%), ammonium (6.9–19%; average = 13%), and chloride (<Detection limit–4.8%; average 0.6%) account for the rest of the particle mass. Analyses of the 37 field studies in urban and anthropogenically influenced rural/remote area shown in Figure 3 indicate the ubiquity and dominance of oxygenated species in organic aerosols, of which a major fraction is likely to be secondary in nature.

Ranges of the mass of total fine particle (roughly those particles with diameters less than 2 μm) in the troposphere at ground level are:

Remote	<5 $\mu\text{g m}^{-3}$
Nonurban continental	15 $\mu\text{g m}^{-3}$
Urban	50 $\mu\text{g m}^{-3}$
Urban (heavily polluted)	>100 $\mu\text{g m}^{-3}$

As expected, highest global concentrations of atmospheric aerosols are found in large urban areas, where total mass concentration levels can routinely exceed 100 $\mu\text{g m}^{-3}$.

Conclusion

Atmospheric aerosols contain the chemical signature of the sources of direct particle emissions into the atmosphere as

well as that of the conversion of gaseous molecules into particulate-phase species. The broadest classification of the chemical components of atmospheric aerosols is into inorganic species (salts, metals), carbonaceous compounds, and water. Many aerosol species are nonvolatile; once deposited in the aerosol phase, they remain there until the particle is eventually removed from the atmosphere. Other species, such as some ammonium salts and a variety of organic compounds, distribute themselves between the gas and aerosol phases in accordance with local atmospheric conditions. Not all particles of the same size at the same location have the same chemical composition, as particles arise from different sources and have different histories in the atmosphere. Particle mass concentrations vary over the globe, from the order of 1 $\mu\text{g m}^{-3}$ in the cleanest air masses to more than 100 $\mu\text{g m}^{-3}$ in polluted urban areas. Understanding the dynamics of the chemical composition of the atmospheric aerosol remains one of the challenges of atmospheric science.

Nomenclature

NMHC Nonmethane hydrocarbons, all hydrocarbons except methane.

VOC Volatile organic compound.

Isoprenoides Compounds derived from and including isoprene and terpenes.

Tg 10^{12} g.

yr year.

Tg yr⁻¹ Teragram per year (unit for emission rates).

OH radical Hydroxyl radical.

NO_x Sum of NO and NO₂.

NO₃ Nitrate radical.

K Kelvin, units for absolute temperature.

hPa Hecto Pascal, unit for pressure.

OH_kalkane Rate constant for reaction of an alkane with OH-radicals.

OH_kalkene Rate constant for reaction of an alkene with OH-radicals.

O₃kalkene Rate constant for reaction of an alkene with ozone.

OH_k Rate constant for reaction of a VOC with OH-radicals.

NO₃k Rate constant for reaction of a VOC with NO₃-radicals.

Cl_k Rate constant for reaction of a VOC with Cl-atoms.

[OH] OH-radical concentration.

τ_{alkane} Atmospheric lifetime of an alkane.

τ_{alkene} Atmospheric lifetime of an alkene.

Synopsis

During the last decades it has been recognized that organic trace gases other than methane play an important role in the chemistry of the troposphere. Aliphatic nonmethane hydrocarbons (NMHCs) are one of the major groups among the wide range of compounds that constitute nonmethane volatile organic compounds (VOCs). Although the total global emission rate of aliphatic NMHC is only a small fraction of all VOC emissions, the uneven spatial and temporal distribution of aliphatic hydrocarbon emissions combined with their high reactivity makes them important contributors to atmospheric chemical reactions in areas with strong emissions such as urban and industrialized regions or areas with strong biomass burning activities. Aliphatic hydrocarbons are also valuable tracers for identifying important atmospheric processes and trace gas sources.

Introduction

Aliphatic hydrocarbons, similar to other volatile organic compounds (VOCs) and carbon monoxide, are major players in a variety of important chemical processes in the atmosphere. They react with hydroxyl (OH) radicals and thus influence the atmospheric balance of reactive radicals and thus the self-cleansing properties of the atmosphere. Their atmospheric oxidation results in the formation of a number of important secondary photooxidants, the arguably most important one being ozone. Other important secondary photooxidants derived from the atmospheric oxidation of aliphatic hydrocarbons include aldehydes, peroxides, ketones, and a wide range of organic nitrogen compounds including peroxyacetyl nitrate. The oxidation of aliphatic hydrocarbons also contributes to formation of secondary organic aerosols (SOAs).

Strictly speaking, the definition of aliphatic hydrocarbons includes a very wide variety of and an extremely large number of compounds. However, for the practical purpose of this article the range of substances will be limited to those aliphatic hydrocarbons that are most abundant in the troposphere or for some other reason of specific interest for the chemistry of

the atmosphere. Furthermore, some specific groups of hydrocarbons such as methane and isoprenoides are treated in separate articles and will therefore be excluded, although they chemically belong to the category of aliphatic hydrocarbons. For the same reason, aliphatic hydrocarbons that are primarily attached to atmospheric particulate matter will not be discussed here. Here the term aliphatic nonmethane hydrocarbon (aliphatic NMHC) will be used for the thus defined group of compounds. Even with these limitations, the number of compounds that fall into the thus defined category of aliphatic NMHC is potentially very large.

Nearly all aliphatic NMHCs that are relevant for the chemistry of the troposphere can be combined into two chemical groups, alkanes and alkenes. The only relevant exception is ethyne, the only alkyne that is of some significance for the chemistry of the troposphere. Alkanes that are relevant have seldom more than eight or nine carbon atoms; the important alkenes generally have less than five carbon atoms. This substantially reduces the number of aliphatic hydrocarbons that are relevant for the chemistry of the troposphere. Furthermore, there are many parallels between different compounds and the main features of the tropospheric

chemistry and distribution of aliphatic hydrocarbons can be derived from a few general principles.

With very few exceptions the atmospheric residence time of aliphatic hydrocarbons is a few days or less, a timescale that does not allow significant large-scale transport. Therefore, aliphatic hydrocarbons have very little direct relevance for the chemistry of the stratosphere and upper troposphere or regions remote from major sources of aliphatic hydrocarbons. This article will discuss the sources, sinks, chemical transformations, and distribution of aliphatic hydrocarbons in the troposphere.

Sources of Atmospheric Aliphatic Hydrocarbons

Overview

There are several global and regional emission inventories available on the Internet. While they are reasonably consistent in the main features such as global totals or global emission patterns, they differ in many details and also present information with varying levels of detail. Moreover, many of these inventories are designed with the use of numerical model simulations of air pollution in mind and therefore often combine different chemical species into lumped categories. Furthermore, establishing emission inventories typically is based on a significant amount of extrapolation from limited sets of observations. Consequently there are substantial uncertainties for total emission rates, speciation, geographical distribution, trends, and seasonal cycles. There is evidence, mainly based on ambient observations that several current inventories tend to underestimate anthropogenic emission rates. This should be kept in mind when using the overview over aliphatic NMHC emissions presented in this article.

For practical and regulatory reasons emission inventories often identify sources of atmospheric trace gases by the type of activity that results in emission, for example domestic heating, transportation, or electricity generation. Sometimes sources are also characterized by the type of material used as fuel or feedstock, for example natural gas, oil, coal, and wood. A further differentiation can be based on distinction between emissions from production, processing, distribution, storage, and usage. [Table 1](#) lists the most important types of sources for atmospheric aliphatic hydrocarbons and some of their subcategories.

Table 1 Sources of atmospheric aliphatic NMHC and their subcategories

Category	Subcategories
Biomass burning	Wildfires, prescribed fires, deforestation, agricultural waste burning, biofuels
Fossil fuel use	Road transportation (exhaust and fugitive emissions), nonroad transportation, fuel production, storage, distribution, solvent production and usage, industrial losses, electricity generation, domestic heating
Biological production	Vegetation, soil emissions, oceanic emissions
Geothermal vents	
Solid waste disposal	

The composition of emissions is determined by the type of process that results in emission as well as the chemical composition of the parent material. Emissions resulting from evaporation or leakage of material containing aliphatic hydrocarbons typically have a composition closely related to that of the parent material. In the case of partial evaporation, often fractionation, depending on vapor pressure of the individual component, occurs. Emissions resulting from incomplete combustion are highly dependent on type of fuel and the efficiency of the combustion process. Reduction of emissions of hydrocarbons from combustion processes is typically achieved by increased combustion efficiency, sometimes by adding a second oxidation step such as catalytic converters in cars. Differences in fuel and combustion process influence not only the total VOC emissions, but also have substantial impact on the composition of the emissions. [Figure 1](#) gives examples of differences in relative composition between some of the major sources of atmospheric aliphatic hydrocarbons.

Emission Rates and Source Distributions

Global average emissions of aliphatic NMHC are presently in the range of 90 to 150 Tg yr⁻¹ with a best estimate of approximately 120 Tg yr⁻¹. [Figure 2](#) gives an estimate of the average contributions of individual NMHC to total emissions. About 40–50% of these emissions are connected to fossil fuel usage, including production, storage, and distribution. Biomass burning contributes between 20 and 30%. However, only part of biomass burning emissions is from wildfires, significant emission also results from various agricultural practices such as burning of agricultural waste, controlled forest burning and use of biofuels, and therefore controlled by human activities. Biogenic contributions to aliphatic NMHC in the atmosphere are emissions from vegetation and oceans. It should be noted that emission rates of aliphatic NMHC from vegetation are small compared to the emission rates for isoprene and terpenoids, but nevertheless contribute to the atmospheric budget of aliphatic NMHC. Oceanic emissions of light alkenes and alkanes are in the range of a few teragram per year, a small fraction of the total global aliphatic NMHC emissions and thus of minor importance for the total budget. However, due to the absence of other sources over remote oceans regions, these emissions can impact the chemistry of the remote oceanic atmosphere. [Table 2](#) lists global average emission rates of light aliphatic NMHC for different source categories. It has been shown recently that geothermal vents are a source for light alkanes, but the magnitude of this source is highly uncertain.

With very few exceptions, source strength estimates for aliphatic NMHC are based on a so-called bottom-up approach where estimates are based on the evaluation of sources. For a few aliphatic NMHC so-called top-down estimates have been made. In these estimates, the emission rates are based on budget considerations and calculation of loss rates. This requires knowledge of representative atmospheric distributions of the individual NMHC, which exists only for the least reactive NMHCs such as ethane and propane. Source estimates derived from such top-down evaluations are, as far as available, included in [Table 2](#).

Figure 1 Comparison of the relative composition of different source categories. ‘Gas vapor’ refers to losses of liquified petroleum gas during distribution and usage. The individual emissions are normalized to the sum of all identified aliphatic NMHC emitted from the specific source category. Data are compiled from McLaren, R., Singleton, D.L., 1996. There are no chemical mechanisms that result in the formation of aliphatic NMHC from other atmospheric trace gases and, with the exception of minor emissions from airplanes, all sources of aliphatic NMHC are located on the ground. Consequently, nearly all emissions occur in the lower levels of the atmospheric boundary layer. High-emission rates of aliphatic NMHC are observed for densely populated regions, major industrialized areas and regions with intense fossil fuel production. Emissions from biomass burning and biological sources are often spread over large areas. Emission of saturated NMHC is mainly associated with fossil fuel production, unsaturated NMHC mainly with incomplete combustion processes, including biomass burning, and areas of dense vegetation (Figure 3).

Temporal Changes in Emission Rates

Emission rates of aliphatic NMHC are tied to a number of factors that change with time. Periodic changes of emissions can be driven by environmental factors such as temperature or human activity patterns. Emissions from transportation peak during morning and afternoon rush hours, fuel and solvent evaporation rates depend on ambient temperature and biogenic emissions can depend on temperature and photosynthesis rate. In some cases, weekly cycles in emissions are created by differences in human activities between weekdays and weekends. Annual cycles are driven directly and indirectly by ambient conditions. Emissions from domestic heating peak during cold seasons, biogenic emission and biomass burning depend on growing cycles as well as temperature, humidity, and rainfall. In most parts of the Northern Hemisphere

Figure 3 Global distribution of the total annual average of emission rates of several light aliphatic NMHC. Data are taken from the Granier, C., Bessagnet, B., Bond, T. et al., 2011. Evolution of anthropogenic and biomass burning emissions of air pollutants at global and regional scales during the 1980–2010 period. *Climate Change* 109, 163–190. doi:10.1007/s10584-011-0154-1.

biomass burning emissions from wildfires and prescribed fires peak between July and October, but in some areas such as Northern Hemisphere Africa and southern Asia the occurrence of dry seasons and agricultural practices cause peak emissions around December and January. The change in global distribution of ethene emission rates shown in **Figure 4** is predominantly the result of seasonal variations of biomass burning and biological activity.

Long-term trends in emission are caused by population growth as well as industrial and technological development. Varying intensity in forest clearing, changes in agricultural practices, and control strategies for wildfires also contribute to secular trends in emission rates. There is no doubt that aliphatic NMHC emissions increased very substantially between the beginning of the industrial age and the last decades of the twentieth century. However, during the last decades the overall

Figure 4 Seasonal change of the global distribution of ethene emission rates. Data are taken from Granier, C., Bessagnet, B., Bond, T., et al., 2011. Evolution of anthropogenic and biomass burning emissions of air pollutants at global and regional scales during the 1980–2010 period. *Climate Change* 109, 163–190. doi:10.1007/s10584-011-0154-1.

trend is no longer obvious. Factors contributing to increased emissions, such as worldwide increase in population, increase in fossil fuel consumption rates, increased worldwide industrialization, and rapid economic developments in India and China and other developing countries are to some extent compensated by investments in emission reduction technologies and improvements in efficiency of fossil fuel usage driven by increasing costs of oil and natural gas. Other factors contributing are the drastic economic and ecological changes in the area of the former Soviet Union and other state-directed economies and efforts to limit greenhouse gas emissions, which also impact emissions of aliphatic NMHC. Overall artificial aliphatic NMHC emissions peaked around 1990 with indication for a slight decrease early in the twenty-first century (Figure 5).

Emission rates from different source categories show varying temporal trends as a result of regulatory measures, development in technology as well as ecological and economical considerations. For example, emission from fossil fuel production increased during the last two decades, while at the same time transportation-related emissions significantly decreased. It is important to realize that the relatively moderate changes in global emission rates of artificial aliphatic NMHC are the result of substantially different trends in different countries. For most developed nations, emissions decreased significantly during the last two decades (Figure 6(a)). This is primarily due to reductions in emissions from road transport (Figure 6(b)). In exceptional cases emissions from developed countries increased substantially as result of emissions from increasing fossil fuel production outweighing reductions in emissions from road transport (Figure 6(b) and 6(c)). For developing countries often changes in emissions from several source categories contribute to overall increasing emission rates. It should be noted that for countries with very moderate changes in overall emission rates, this can be the result of compensating changes in emissions from different source

types. One of the potential consequences is that, even in case of little change in total emissions, speciation and spatial distribution change as can be seen in the change of the global distribution of anthropogenic ethene emissions between 1990 and 2008 (Figure 7). While there are large reductions in emissions from Europe and North America, due to the emission increases in Africa, India, and southern Asia, the change in total global anthropogenic ethene emissions is only about 10%, which is well below the uncertainty of the emission rate estimates.

Most changes in emission rates are gradual, resulting in smooth trends over several years, sometimes decades. A notable exception is emissions from countries with former state-directed economies. In these countries rapid and drastic economic and political changes resulted in large changes of emissions over timescales of less than a decade around 1990. The only source category with frequent large interannual variations in emission rates is biomass burning, especially emissions from wildfires. This is the result of substantial interannual variations in temperature, humidity, and rainfall distributions.

There are several emerging technologies such as mining of oil sands, hydraulic fracturing for natural gas mining, and nontraditional usage of biological materials as fuels, which result in emissions of aliphatic NMHC. Most likely these sources will become significant in the future. However, at present these emissions are not sufficiently well characterized to allow meaningful quantitative predictions.

Atmospheric Reactions

Tropospheric Removal

The only relevant removal of aliphatic NMHC in the troposphere occurs by gas phase reactions, predominantly initiated

Figure 5 Trend of global annual average emission rates for aliphatic NMHC. 'Other' includes minor anthropogenic emissions such as solvent use as well as natural sources with the exception of wild fires, which are included in biomass burning. Data are taken from the EDGAR emission inventory.

Figure 6 Example for temporal development of aliphatic NMHC emissions for selected countries. Shown are the changes of total annual emissions (a) as well as for two major source categories, road transportation (b), and fugitive emissions (c). The emissions are given as percentage of the total aliphatic NMHC emissions in 1970. Please note that emissions from road transportation for the United States are on a secondary axis. Data are taken from the EDGAR emission inventory.

Figure 7 Change in global distribution of ethene emissions for anthropogenic sources between 1990 and 2008. Data are taken from the MACCity emission inventory.

by OH radicals. For alkanes and ethyne the reaction with OH radicals is on global average the dominant loss mechanism. Alkenes react also with ozone, although this reaction generally is less important than removal by OH radicals. To a minor extent the reaction with chlorine (Cl) atoms, bromine (Br) atoms, and the nitrate (NO_3) radicals contribute to tropospheric removal of aliphatic NMHC. Although these latter

reactions are on global average of minor importance they can be highly relevant under specific conditions.

In the lower polar troposphere during spring Cl atom concentrations frequently cause a clearly visible depletion in the concentration of nearly all aliphatic NMHCs. Similarly, under these conditions Br atom reactions contribute significantly to the removal of ethyne and light alkenes. Reactions with halogen

atoms can also have significance for loss processes of aliphatic NMHC in coastal regions heavily impacted by industrial emissions. Due to the extremely low concentrations of aliphatic NMHC in the stratosphere, stratospheric reactions of aliphatic NMHC contribute only marginally to the chemistry of the stratosphere and have very little impact on the overall budget of aliphatic NMHC.

For most aliphatic NMHCs, the rate constant for reaction with the nitrate radical is too slow to be of relevance for the troposphere. However, at high nitrate radical concentrations, which can occur at night in regions with substantial sources of nitrogen oxides (NO_x), this reaction can be an important loss mechanism for alkenes. The reactivity of alkenes toward the nitrate radical increases drastically with increasing alkyl substitution at the double bond and for these highly reactive alkenes' reaction with the nitrate radical can be an efficient loss process at night. In general, this is less important for the chemistry of the alkenes treated here, but can be highly relevant for reactions of isoprene, terpenes, and related compounds of predominantly biogenic origin.

The rate constants for atmospheric reactions of aliphatic NMHC depend on the type of reaction partner as well as on the chemical structure of the NMHC. These rate constants range from effectively zero to the collision-frequency limit. With very few exceptions, the relevant rate constants for reactions of aliphatic NMHC in the troposphere have been subject to detailed laboratory studies and are well understood. There are several algorithms that allow predictions of reaction rate constants based on structure-reactivity relations. Table 3

presents examples of rate constants for reaction of some of the most important aliphatic NMHCs with OH radicals, ozone, chlorine atoms, and the nitrate radical. The rate constants are given for standard conditions; that is a temperature of 298 K and a pressure of 1000 hPa. Most of these are temperature dependent. Since the temperature in the troposphere varies substantially, this has to be considered when using rate constants for calculations under nonstandard conditions. With extremely few exceptions the rate constants do not depend on pressure for the pressure range that is relevant for the troposphere.

As mentioned above, tropospheric removal of alkanes is nearly entirely due to reaction with OH radicals. Thus their atmospheric lifetime, τ_{alkane} , can be calculated from the rate constant for reaction with OH radicals, $^{\text{OH}}k_{\text{alkane}}$, and the OH-radical concentration, $[\text{OH}]$:

$$\tau_{\text{alkane}} = (^{\text{OH}}k_{\text{alkane}} * [\text{OH}])^{-1} \quad [1]$$

In the case of alkenes, the reaction with ozone also has to be considered and we obtain:

$$\tau_{\text{alkene}} = (^{\text{OH}}k_{\text{alkene}} * [\text{OH}] + ^{\text{O}_3}k_{\text{alkene}} * [\text{O}_3])^{-1} \quad [2]$$

The rate constants for reactions of individual aliphatic NMHC range over several orders of magnitude depending on chemical structure. Consequently atmospheric lifetimes of aliphatic NMHC cover a wide range, from several months for ethane to less than 1 h for some of the most reactive alkenes. Figure 8 gives an overview of the average atmospheric lifetime for some of the most abundant aliphatic NMHCs.

Table 3 Rate constants for the reaction of some alkanes and alkenes with OH radicals, ozone, chlorine atoms, and NO_3 radical at 298 K and 1 atm total pressure of air

Compound	OH $^{\text{OH}}k$ (10^{-12} cm^3 $\text{molecule}^{-1} \text{ s}^{-1}$)	Ozone $^{\text{O}_3}k$ (10^{-17} cm^3 $\text{molecule}^{-1} \text{ s}^{-1}$)	Chlorine $^{\text{Cl}}k$ (10^{-11} cm^3 $\text{molecule}^{-1} \text{ s}^{-1}$)	NO_3 $^{\text{NO}_3}k$ (cm^3 $\text{molecule}^{-1} \text{ s}^{-1}$)

Figure 8 Atmospheric lifetimes of selected aliphatic NMHC. The calculations are based on rate constants from Table 3, average OH-radical concentration of 1×10^6 radicals cm^{-3} , and average ozone volume mixing ratio of 30 nmol mol^{-1} .

The concentrations of OH radicals and ozone in the troposphere exhibit a very high spatial and temporal variability. Furthermore, many of the rate constants for reaction of hydrocarbons with OH radicals or ozone have significant temperature dependence. Therefore, the atmospheric lifetimes of aliphatic NMHC are highly dependent on time and location and the values presented in Figure 8 can only serve as a general guideline to average values. Due to the short atmospheric residence time for most aliphatic NMHC, conditions representative for relatively small temporal and spatial scales often determine their removal rates. It is also important that OH-radical and ozone concentrations as well as temperature exhibit strong, systematic variations with season, latitude, and altitude, which result in corresponding systematic variations of the local atmospheric lifetimes of hydrocarbons.

Generally the atmospheric residence times of aliphatic NMHC decrease from high toward low latitudes and they are longer in winter than in summer. The summer to winter increase is more pronounced at high latitudes than at low latitudes. Furthermore, the removal rates of aliphatic NMHC exhibit a very pronounced diurnal variability, with the fastest losses occurring around noon and very slow, often negligible removal rates during night.

Formation of Secondary Pollutants

Ultimately all atmospheric NMHCs are oxidized to carbon dioxide and water. However, this occurs via complex reaction sequences comprised of many individual steps and several of the products formed are important for the chemistry of the atmosphere. The oxidation of aliphatic NMHC plays a major role in the formation of tropospheric ozone and other photooxidants such as peroxides and peroxyacetyl nitrate. Furthermore, aliphatic NMHCs are precursors for a variety of

oxygenated compounds such as aldehydes, ketones, and carboxylic acids as well as organic nitrates. Oxidation of aliphatic NMHC also contributes to formation of SOAs, but it should be noted that the yield of condensable organic compounds from atmospheric oxidation of most aliphatic NMHCs is very small and only oxidation of aliphatic NMHCs with six or more carbon atoms has significant yields for SOA.

Here we give a brief overview of the reactions that result in the formation of the most important oxidation products of aliphatic NMHC. Since the initial reactions of alkanes and unsaturated compounds are fundamentally different, these two groups of compounds will be treated separately, although the types of products and the subsequent reactions show similarities.

Alkanes. The reaction of alkanes (RH) with OH radicals is entirely by abstraction of a hydrogen atom from one of the carbon atom and results in the formation of an alkyl radical:

For most aliphatic NMHCs, this reaction can occur on different, not equivalent carbon atoms. Generally, the most stable alkyl radical, that is the one with the higher number of alkyl groups attached, is formed preferentially. For example, in the reaction of propane with OH radicals the 2-propyl radicals will be preferred over the 1-propyl radical.

In the atmosphere, this hydrogen atom abstraction initiates a chain reaction that, depending on the concentration of other atmospheric trace constituents, results in the formation of several other radicals and to some extent recycles the OH radical.

Following hydrogen abstraction is a rapid addition of an oxygen molecule:

Figure 9 Modeled global distributions of light aliphatic NMHC in the lowest levels of the atmosphere.

In the presence of significant levels of NO, as a rule of thumb more than 40 pmol/mol, the reaction chain proceeds predominantly via [reaction \[III\]](#)

For peroxy radicals with larger alkyl groups to some extent addition of NO, followed by isomerization and formation of an alkyl nitrate is an alternative pathway.

For small alkyl groups, e.g., ethyl or propyl, the [reaction \[IV\]](#) only contributes a few percent or less, but for large alkyl groups with six or more carbon atoms this pathway can contribute in the range of 10–35%. Thus [reaction \[IV\]](#) can be an important source for alkyl nitrates in the atmosphere.

At low NO levels the alkylperoxy radical reacts with other peroxy radicals ($\text{RO}_2^\bullet$ or $\text{HO}_2^\bullet$) as illustrated in [reaction \[V\]](#).

The reaction of the alkoxy radical (RO) is highly dependent on the structure of the alkyl group. For radicals of the $\text{RR}'\text{HCO}^\bullet$ or $\text{RH}_2\text{CO}^\bullet$ type, abstraction of a hydrogen atom by an oxygen molecule is the preferred route:

Alternatively, scission of a C–C bond forming a carbonyl compound and an alkyl radical or isomerization to a hydroxy alkyl radical can occur. In the atmosphere, the radical formed by both alternative processes will rapidly add an oxygen molecule and the newly formed peroxy radical will undergo a reaction sequence analogous to that outline above.

Depending on the concentration of the reactants, the $\text{HO}_2^\bullet$ radical formed by [\[VI\]](#) will react with NO, ozone, or other peroxy radicals. In the presence of NO, the reaction will be similar to [reaction \[III\]](#) and recycles the OH radical:

At very low NO concentrations the reaction sequence proceeds analogous to [reaction \[V\]](#) or by reaction with ozone:

[Reactions \[VII\] and \[VIII\]](#) regenerate the OH radical consumed in the initial reaction step. Consequently, the atmospheric oxidation of alkanes is an OH radical-initiated chain reaction. It is important that the conversion of NO into NO_2 by [\[III\]](#) and [\[VII\]](#) is not a net loss of NO since during daytime NO is regenerated by photolysis of NO_2 .

The oxygen atom formed in this reaction recombines in the atmosphere with an oxygen molecule resulting in the formation of ozone. The efficiency of the formation of ozone from atmospheric oxidation of hydrocarbons thus is highly dependent on NO concentration.

Alkenes. Although the initial step of the reaction of unsaturated aliphatic hydrocarbons is an addition to the double bond instead of abstraction of a hydrogen atom there are many similarities to the oxidation of saturated NMHC. The most obvious difference is that alkenes react very rapidly with OH radicals, often by orders of magnitude faster than the alkanes. The addition of the OH radicals to an alkene results in the formation of an β -hydroxyalkyl radical, which then, similar to alkyl radicals, in the atmosphere rapidly adds an

Figure 10 Average concentration of selected aliphatic NMHC in the 1980s at locations subject to different levels of anthropogenic emissions. '39 US cities' represents the average of studies in 39 major cities in the United States; York University is located in a suburban area in the Greater Toronto area, Ontario, Canada; Dorset is a semirural region in southern Ontario; Fraserdale is a remote station in central Ontario; Alert is a background station in the Canadian Arctic. Data are from: Seila, R.L., Lonneman, W., Meeks, S., 1989. Determination of C2 to C12 Ambient Hydrocarbons in 39 U.S. Cities From 1986 Through 1989, US Environmental Protection Agency Official Research Division Report EPA 600/058, pp. 53–89; Jobson, B.T., Wu, Z., Niki, H., Barrie, L., 1994. Seasonal trends of isoprene, C2–C5 alkanes, and acetylene at a remote boreal site in Canada. *Journal of Geophysical Research* 99, 1589–1599; Rudolph, J., unpublished results.

oxygen molecule forming a β -hydroxyalkylperoxy radical as shown here using ethene as example

These β -hydroxyalkylperoxy radicals react very similar to the alkylperoxy radicals (reaction [III]). In the presence of NO, the preferred reaction is the formation of a β -hydroxyalkoxy radical.

Analogous to the alkane oxidation an alternative reaction pathway at very low NO concentration is the reaction with other peroxy radicals. In the atmosphere the β -hydroxyalkoxy radicals either react with molecular oxygen, decompose, or isomerize, similarly to the alkylperoxy radicals (see above).

One major difference between the atmospheric chemistry of alkanes and alkenes is that alkenes react with ozone. This reaction results in formation of a carbonyl compound and an excited Criegee intermediate ($>\text{COO}^*$).

In the troposphere the excited Criegee intermediate can undergo a variety of different reactions, the most important channels are collisional deactivation, decomposition, or isomerization. These reaction channels branch further into formation of a variety of more or less complex molecules and radicals, depending on the structure of the alkene precursor. One very important reaction channel is the formation of OH radicals. Especially under conditions when direct photochemical formation of OH radicals is slow, such as at night or in the early morning, alkene ozonolysis can be a relevant source of free radicals.

Qualitatively the effect of atmospheric oxidation of alkenes on the chemistry of the troposphere is very similar to that of alkanes. However, due to their higher reactivity, alkenes often play a more important role for the chemistry of the troposphere, especially in areas directly influenced by strong, local, or regional emissions. Furthermore, the

oxidation of alkenes generally results in more complex molecules and products, increasing the complexity of the chemistry of the troposphere.

Atmospheric Distribution

During the last four decades a variety of techniques to quantitatively determine hydrocarbons in air have been developed, providing the possibility for detailed studies of their atmospheric distribution. It should be noted that measurement techniques for aliphatic NMHC seldom specifically target this group alone, but generally aim at analysis of NMHC in general. The most widely used and versatile measurement technique for aliphatic hydrocarbons is gas chromatography in combination with cryogenic preconcentration of the hydrocarbons prior to the chromatographic separation. This method allows analysis of a broad range of hydrocarbons with detection limits in the lowest pmol mol^{-1} range, sufficient for reliable measurements of relevant concentrations of aliphatic hydrocarbons under most conditions. Generally, whole air samples are collected in airtight sample containers and transferred to the laboratory for analysis. During the last two decades *in situ* instrumentation has also been used in a substantial number of studies. In addition to modified gas chromatographic instrumentation mass spectrometric methods such as Proton Transfer Reaction Mass Spectrometry (PTRMS) are widely used. Mass spectrometric methods have become extremely valuable for measurements that require high time resolution such as mobile platforms or flux and gradient measurement.

Due to the numerous measurement series of aliphatic NMHC in the troposphere that have been conducted during the last decades, there is good understanding of their basic temporal and spatial distribution. However, due to the short atmospheric residence time of most aliphatic NMHCs there is often very large, sometimes seemingly random

Figure 11 Example for correlation between mixing ratios of aliphatic NMHC. Data points represent the average mixing ratios for 28 US cities. variability. Consequently, measurements of their concentrations are generally only representative on local or regional scales. Only for some of the least reactive of the aliphatic NMHCs reasonably well-defined and representative global distribution have been derived from atmospheric observations.

Concentrations of aliphatic NMHC range from several ten nanomoles per moles in urban, polluted regions to a fraction of nanomoles per moles and less in the remote Southern Hemisphere. The distribution of the concentration of aliphatic NMHC in the troposphere is determined by the interaction of three processes, (1) emissions; (2) atmospheric transport, dilution, and mixing; and (3) removal. Since all three processes show a complex dependence on time and location, the very substantial variability of the concentrations of aliphatic NMHC in the troposphere is not surprising.

Nevertheless, a substantial part of this variability is systematic. Today, a reasonable overview of the basic features of the atmospheric distribution of aliphatic NMHC can be obtained from computer-based numerical model simulations. While these model calculations seldom are able to describe all details of the atmospheric variability of NMHC concentrations, they have developed to a stage where they can provide a good overview. Numerical models are used to calculate the atmospheric distribution of NMHC on a wide range of spatial and temporal timescales.

Large-scale distributions. Figure 9 presents modeled global ground level distributions for aliphatic NMHC with average atmospheric lifetimes ranging from about 2 month (ethane) to less than 1 day (propene). The differences between January and July are mainly due to the seasonal variability of the OH-radical concentration, but also changes in atmospheric transport patterns and seasonal variation of emission rates, for example from biomass burning or vegetation. Atmospheric concentrations of aliphatic NMHC rapidly decrease with increasing distance from the source regions. The concentration gradients are the result of atmospheric mixing and chemical loss processes. The strong gradients of the latitudinal distributions between midnorthern latitudes and the Southern Hemisphere reflect primarily the large-scale distribution of the sources, but it has to be remembered that atmospheric transport and removal processes also play

a major role in determining the shape of the latitudinal profiles. Specifically, the atmospheric degradation of aliphatic NMHC by reaction with OH radicals is faster at low latitudes, a consequence of the latitudinal gradient of the OH-radical concentration. Consequently, seasonal cycles in the Southern Hemisphere are shifted by 6 month relative to those in the Northern Hemisphere and the seasonal variability in the tropics is less pronounced than at midlatitudes. The steepness of the gradients between source regions and remote areas depends on reactivity of the trace gas and the change in concentration from areas with high emission rates toward background ratios is more pronounced for NMHC with high reactivity. The result is an increase in systematic as well as seemingly random variability of mixing ratios with increasing NMHC reactivity. Figure 10 shows an example for the change in observed mixing ratios for locations subject to different levels of artificial trace gas emissions.

One frequently observed consequence of differences in NMHC reactivity is the systematic change in the ratios of NMHC concentrations with increasing NMHC processing. This is used to estimate the extent of photochemical processing or photochemical age of the NMHC ('hydrocarbon clock'). However, due to the complex interaction of transport and processing the photochemical age derived from ratios of hydrocarbon concentrations is sometimes difficult to interpret. In the absence of significant photochemical loss, for example, in close proximity to strong NMHC sources, often a strong correlation between the mixing ratios of different aliphatic NMHC can be seen (Figure 11). This is the result of variability of emission rates, atmospheric mixing, and dilution. Since the relation between different trace gases ('fingerprint') is often characteristic for specific source types this can be used to

Figure 14 Trend of butadiene mixing ratios at different types of locations in the United Kingdom. For comparison also the average of observations at several locations in California are included. Please note that the scale for roadside observations is on a secondary axis. Average data for California are taken from the California Environmental Protection Agency Air Resources Board (<http://www.arb.ca.gov/adam/toxics/statepages/butastate.html>). Data for the UK are from Dollard, G.J., Dumitrean, P., Telling, S., Dixon, J., Derwent, R.G., 2007. Observed trends in ambient concentrations of C2–C8 hydrocarbons in the United Kingdom over the period from 1993 to 2004. Atmospheric Environment 41, 2559–2569.

Figure 15 Mixing ratios of selected aliphatic NMHC at urban and rural locations in Pakistan (Karachi) and China (GZ, Guangzhou a highly industrialized large City; DM, Denghou Mountain, a rural area in the Pearl River Delta) between 1999 and 2005. Included for comparison are average mixing ratios for 28 US cities measured between 1999 and 2005. Data are taken from Baker, A.K., Beyersdorf, A.J., Doezema, L.A., et al., 2008. Measurements of nonmethane hydrocarbons in 28 United States cities. *Atmospheric Environment* 42, 170–182; Tang, J.H., Chan, L.Y., Chan, C.Y. et al., 2008. Mixing ratios of volatile organic compounds (VOCs) in the atmosphere of Karachi, Pakistan. *Atmospheric Environment* 36, 3429–3443.

identify the contributions of different source types to air pollution ('source apportionment').

The vertical distributions of aliphatic NMHC depend strongly on local and regional emission rates and the atmospheric lifetime of the compound. Figure 12 shows examples for the decrease in mixing ratios of aliphatic NMHC between ground level and free troposphere over a region with high emission rates. For regions with low or insignificant sources the gradients are often less pronounced and for very remote regions vertical gradients of the least reactive aliphatic NMHC are often insignificant (Figure 13).

In urban areas, the concentrations of aliphatic NMHC often show distinct diurnal patterns with high values in the morning and lower concentrations in the afternoon. Although OH-radical concentrations have distinct diurnal variations, with high values around noon and in early afternoon, and very low values at night, in the late evening, and early morning, the diurnal variability of the chemical removal rate is very seldom the main driving force behind this diurnal variability. Very often the diurnal cycle of aliphatic NMHC is driven by diurnal variations in atmospheric transport or mixing processes and the emission rates, fully consistent with the finding of generally very similar composition pattern in morning and afternoon, independent of the reactivity of the aliphatic NMHC.

Secular trends. Due to the high spatial and temporal variability of most aliphatic NMHCs secular trends in their atmospheric mixing ratios differ between regions. For Western Europe and North America the significant decrease in emissions resulted in a significant reduction in the atmospheric levels of most aliphatic NMHCs (Table 4; Figure 14). For

most developing countries present-day levels of air pollution in major cities significantly exceed those in developed countries (Figure 15). There is some evidence that during the last decade increasing efforts in air pollution mitigation in developing countries reduce the upward trend in pollution levels. However, due to the limited extent of systematic, consistent monitoring of aliphatic NMHC in most developing countries the presently available data do not allow identification of representative secular trends.

Only for ethane, the least reactive of the aliphatic NMHC, observations allow deriving a meaningful global trend. During the last two decades the global average mixing ratio decreased by about $0.15 \text{ nmol mol}^{-1}$ from nearly $0.8 \text{ nmol mol}^{-1}$ in the mid 1980s.

This article is a revision of the previous edition article by I Barnes, K H Becker, volume 6, pp 2376–2385, © 2003, Elsevier Ltd.

Synopsis

Aromatic hydrocarbons are an important class of organic compounds found in the atmosphere, which are highly reactive and have large emission rates, particularly in urban environments. The article describes the gas-phase atmospheric chemistry of the atmospherically most important aromatic hydrocarbons, benzene, toluene, ethyl benzene, and the isomers of xylene that are collectively often referred to as BTEX. The article discusses the emission sources and atmospheric gas-phase degradation processes of BTEX, which have important implications for photooxidant and secondary organic aerosol formation in the troposphere.

Introduction

Aromatic hydrocarbons are an important class of organic compounds found in the atmosphere, which are highly reactive and have large emission rates. It has been estimated that aromatic species contribute about 10% to the total global anthropogenic nonmethane organic carbon (NMOC) emissions, the major source being car exhaust from gasoline-powered vehicles, with a significant contribution also from solvent usage. The observation that biomass burning represents a significant source of aromatics has attracted special attention in recent years, since such processes occur on a global scale. Natural, minor sources of aromatics such as emission from soils and plants have also been identified. The emission of aromatics will therefore have an impact on tropospheric processes on local, regional, and global scales.

In many urban areas, emissions of volatile organic compounds (VOCs) and NO_x , when combined under meteorological conditions that favor smog formation, can lead to the formation of ground-level ozone and particulate matter (PM) at harmful levels. Aromatic hydrocarbons make a significant contribution to the formation of ozone and other photooxidants in urban atmospheres. It has been estimated that the percentage contribution of aromatic hydrocarbons to ozone production can be between 30 and 40%. Such a high contribution would make the aromatics the most important class of hydrocarbons with regard to photochemical ozone formation. However, it should be borne in mind that the oxidation mechanisms of aromatic hydrocarbons are still imprecisely known, and verification of such estimates is necessary. In addition to their high atmospheric photochemical reactivity and their consequent major influence on the formation of tropospheric ozone and on the oxidizing capacity of the atmosphere, it is now firmly established that the photochemistry of aromatic compounds leads to the formation of secondary organic aerosols (SOAs), which are known to be harmful to human health, reduce visibility, and can contribute to climate change. In fact, studies have shown that the atmospheric organic aerosol formation potential of whole gasoline vapor can be accounted for solely in terms of the aromatic fraction of the fuel. As emissions of aromatics are concentrated in urban areas, where many people live and work, the

formation of SOAs becomes a more acute problem. With regard to health effects, benzene, a ubiquitous aromatic environmental contaminant, is hematotoxic, clastogenic, and leukemogenic in humans and produces bone marrow toxicity and various types of cancer in animals. The reason for the carcinogenesis of benzene is still not entirely clear and it has been classified as a Group-A human carcinogen by the US Environmental Protection Agency. Laboratory studies have also shown that the photooxidation of other aromatic hydrocarbons leads to the formation of mutagenic products.

Presented here is a brief overview of the atmospheric composition and gas-phase chemistry of aromatic hydrocarbons concentrating mainly on benzene, toluene, the xylene isomers, and ethyl benzene, since these rank highly among the most important aromatic hydrocarbons emitted to the atmosphere. This group of aromatic hydrocarbons is often referred to as BTEX in the literature. Since the subject is complex, the reader is encouraged to consult the recent articles and books listed in the reading material for coverage in depth on particular aspects of aromatic hydrocarbon chemistry covered here.

Structure and Concentration in the Atmosphere

The simplest of the aromatic hydrocarbons is benzene, which has a hexagon ring structure with three 'double bonds' in the ring. In the aromatic benzene ring, these 'double bonds' are fully conjugated and consequently the compound is relatively stable. All carbons are sp^2 hybridized, and each π orbital overlaps, to an equal extent, its two neighbors. The consequently delocalized electrons form a π cloud above and below the ring. In the molecular structure of benzene all six C–C bonds are equal and all bond angles are 120° . The C–C bond length in benzene is 0.139 Å, between the values for the single (0.147 nm) and the double bond (0.134 nm) in butadiene. All of the three structures shown here for benzene are equivalent.

The generic term for substituted benzenes is arene. An arene, as a substituent, is referred to as an aryl group, abbreviated Ar. The parent aryl substituent is phenyl, C_6H_5 . There are three possible arrangements of disubstituted benzenes. These are described by the prefixes 1,2 (*ortho*-, or *o*-, Greek: straight) for adjacent substituents, 1,3 (*meta*-, or *m*-, Greek: transposed) for 1,3-disubstitution, and 1,4 (*para*-, or *p*-, Greek: beyond) for 1,4-disubstitution. The substituents are listed in alphabetical order. **Figure 1** lists the structural formula, International Union of Pure and Applied Chemistry (IUPAC), and common names of the more prevalent types of aromatic hydrocarbon found in the atmosphere.

Of the 32 most prevalent nonmethane hydrocarbons (NMHCs) observed in urban air, 7 are aromatic hydrocarbons. Toluene is often the most abundant aromatic compound in urban air accounting for around 6% of the observed NMHC. A wealth of data now exists on aromatic hydrocarbon composition and concentration in the atmosphere and the listed literature can be used to access this information. Atmospheric concentrations of aromatic hydrocarbons in urban areas in Europe and North America are often in the ppb range, for example, measured concentrations for benzene, toluene, the xylene isomers, and ethyl benzene are typically in the ranges 1–9, 1–17, 0.3–10, and 0.3–2 ppb, respectively. Recent measurements in Asian cities and metropolitan areas show that the BTEX levels in these areas are often much higher whereby a large fraction of the emissions comes from the use of coal as a domestic fuel. In rural and marine regions, the concentrations are generally below 0.5 ppb.

Table 1 shows an example of the typical VOC composition of Los Angeles morning air in October 1995, with the percentages of the contributions from alkanes, alkenes, aromatics, and other NMHCs. The percentage of OH reactivity (rate coefficient weighted) for each individual compound and compound class group is also shown. **Table 2** shows a comparison of total nonmethane organic compounds (TNMOCs) and percentile distribution of aromatic hydrocarbons for selected European locations. Both tables demonstrate

the high contribution of aromatic compounds to the NMOC mix, particularly in urban environments where the major sources occur. The emissions of aromatic hydrocarbons are overwhelmingly anthropogenic in origin; major sources are the evaporation of fuels, automobile tailpipe exhaust, and industrial processes – in particular, solvent utilization. In many instances, the measured aromatic hydrocarbon composition resembles very closely the aromatic hydrocarbon signature obtained from studies on the NMOC emissions from automobiles, earmarking on-road vehicles as the leading, if not major, source of urban aromatic hydrocarbons. In rural areas where emissions from biogenics dominate the contribution from aromatic hydrocarbons is much lower. In urban areas and suburban areas with a high biomass contribution the measured atmospheric NMOC often resembles a combination of the expected anthropogenic and biogenic emission signatures for the sources present in that particular region.

Biomass burning represents a small but significant emission source of aromatic hydrocarbons, in particular benzene. Plants are known to emit unsaturated compounds containing an aromatic ring and microorganisms can produce benzene and toluene. It has also been shown quite recently that some plants under stress situations emit toluene. At present it is not possible to quantify the emissions of simple aromatic hydrocarbons from the biosphere, but the indications are that the contribution is small.

Estimations of global emissions of aromatics range from 18.7 (17.1% of the total anthropogenic nonmethane volatile organic compounds (NMVOCs) emissions) to 25 teragrams per year, with benzene and toluene alone constituting 25% of the total anthropogenic NMVOC emissions. Regulations in industrialized countries are helping to reduce the aromatic content of fuel; however, even if the content is lowered to about 20 mass percent, the continually increasing global oil demand will keep the global emissions of aromatic hydrocarbons from fossil fuel combustion at a high level. The rapid urbanization rate, growth of megacities, and economic improvements in many parts of Asia are coupled with increasing levels of

pollution and unless stringent control regulations are enforced high levels of aromatic hydrocarbons will remain a problem in these areas for decades to come.

Chemical Transformation Mechanisms in the Atmosphere

Main Oxidants and Relative Importance

The gas-phase oxidation of organic compounds in the troposphere is initiated by reactions with OH and NO₃ radicals, O₃ and potentially Cl atoms and ground state oxygen O(³P) atoms, and in some instances by photolysis at wavelengths longer than 290 nm. Since benzene and the mono-, di-, and trialkyl-substituted benzenes absorb very little of the sunlight present in the troposphere, loss through photolysis is unimportant in the urban atmosphere. The reaction of aromatic hydrocarbons with O(³P) atoms is also of negligible importance. Average Cl atom concentrations will generally not be high enough, particularly in urban environments, to play any significant role in the degradation of aromatic hydrocarbons and consequently such reactions are not considered here.

The relative importance of the other reaction pathways depends on the atmospheric concentrations of the reaction initiators (O₃, OH, NO₃) and their rate coefficients with the individual aromatic hydrocarbon. Because of the high variability of pollutant concentrations and the diurnal cycle in solar radiation, the atmosphere concentrations of O₃, OH, and NO₃ can vary considerably in time and space. Table 3 lists rate coefficients for reactions of a selection of aromatic hydrocarbons, with O₃, OH, and NO₃ for 298 K and 1 atm total pressure. It is instructive to compare the lifetimes of the aromatic hydrocarbons for typical concentrations of the oxidant species, which can occur during daylight and nighttime hours in a polluted urban atmosphere; such a comparison is made in Table 4.

It is evident from Table 4 that the oxidation of benzene and the alkyl-substituted benzenes in the atmosphere is initiated almost exclusively by reaction with OH radicals, the

contribution from NO₃ being extremely small and that from O₃ negligible. Reaction with O₃ is of any significance only for aromatic alkenes such as styrene. Reaction with NO₃ radicals is important for aromatic alkenes and also aromatic hydrocarbons containing hydroxyl groups (e.g., phenol, cresol isomers, etc.). At night this removal process dominates the removal of

these compounds under the given conditions. However, under certain circumstances the NO₃ reaction can dominate the removal of hydroxybenzenes, and also contribute to the removal of aromatic alkenes during daytime. The removal process can be particularly important at low sun angles, when the NO₃ photolysis loss becomes slow enough to allow the

Table 4 Calculated lifetimes for selected aromatic hydrocarbons for reaction with OH and NO₃ radical and O₃ concentrations representative of a polluted atmosphere

NO₃ concentration to build up to levels where it can effectively compete with the OH reactions.

As can be seen in Table 4, with the exception of benzene most aromatic hydrocarbons react fairly rapidly with OH and have atmospheric lifetimes in the range of hours to days, so that atmospheric degradation will be initiated in fairly close proximity to the emission source. Benzene with a lifetime of several days can be transported to hundreds of kilometers.

Primary Reaction Steps

As indicated above, reaction with OH radicals dominates the tropospheric oxidation processes of aromatic hydrocarbons. As shown in Figure 2 the reaction proceeds by two pathways: (1) OH radical addition to the aromatic ring to form a hydroxycyclohexadienyl radical, i.e., an OH-aromatic adduct, which can thermally decompose back to reactants or undergo further reactions to products, and (2) H-atom abstraction from the C–H bonds of alkyl substituent groups.

The rate coefficient for attack at a methyl substitution is of the order of $6 \times 10^{-13} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$. It generally accounts for ≤10% of the overall reaction and becomes increasingly less important with alkyl substitution, since the rate of OH addition to the ring increases. The radicals resulting from H-atom abstraction from alkyl groups of substituted

benzenes undergo reactions analogous to those for alkyl radicals generated from the oxidation of alkanes. The oxidation results mainly in the formation of ring-retaining aromatic aldehyde products (as shown in Figure 3 for toluene). Small yields of aromatic nitrate compounds can also be generated from reaction of the alkyl peroxy radicals with NO, e.g.,

Addition of OH to the aromatic ring is by far the major reaction pathway. Depending on the symmetry of the aromatic compounds, there can be up to six distinct addition points for the OH group. The position of attack relative to an existing substitution is favored in the following order: *ortho*- > *para*- > *ipso*- > *meta*-.

OH-aromatic adducts have been observed spectroscopically and the reactions of the OH-benzene, OH-toluene, and OH-xylene adducts with NO, NO₂, and O₂ have been studied. The adducts do not appear to react with NO, but reaction with O₂ and NO₂ is observed with rate coefficients between $(1.8\text{--}20) \times 10^{-16}$ and $(2.5\text{--}3.6) \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$, respectively. In the atmosphere, reaction of the adduct with O₂ will dominate; however, in laboratory studies with high NO₂ concentrations, both reactions can be important.

The reactions of the OH-aromatic adducts with O₂ are complex, and various different mechanisms have

**Figure 2** Primary pathways in the OH-radical initiated oxidation of aromatic hydrocarbons using toluene as an example.**Figure 3** Reactions of the hydroxycyclohexadienyl radical (OH-aromatic adduct) with O₂.

been proposed to account for the observed products and experimental observations. The multitude of different hydroxy-peroxy radicals which can be generated by addition of O_2 to the OH-aromatic adduct are shown in Figure 4, taking toluene as an example.

Figure 5 summarizes various possible reaction pathways of the OH-aromatic-peroxy radicals, which have been postulated to explain the products observed in the OH-radical initiated oxidation of aromatic hydrocarbons using benzene (1) as an example. For reasons of simplicity and clarity, only formation of a β -hydroxy-peroxy radical (3) via the addition reaction of O_2 with the OH-benzene adduct (2) is shown, since this is considered to be the major pathway, not only for benzene but also for other alkyl-substituted benzenes.

Reaction of O_2 with the OH-aromatic adduct can also lead to products other than a hydroxy-peroxy radical (4). A phenolic product (4) and HO_2 can be formed by attack at the H-atom α - to the hydroxyl group. The attack of O_2 directly at the OH group may generate an aromatic oxide (5) and HO_2 . The aromatic oxide (5) is in equilibrium with the oxepin (6); photolysis of these compounds is also known to yield phenolic products (4), and reaction with OH is known to produce diunsaturated dicarbonyls (8), however, the route producing the aromatic oxide (5) is not considered to be important and has only been shown for completeness.

Such diunsaturated dicarbonyls can also be produced if the β -hydroxy-peroxy radical (3) reacts via 'conventional' atmospheric peroxy radical reactions, i.e., reaction with NO to form an oxy radical followed by ring opening to form (8). Recent work indicates that the reaction of OH-aromatic-peroxy radicals such as (3) with NO is slow and will not be

important under atmospheric conditions. In laboratory studies with high NO levels, the process may occur and these compounds have indeed been observed in some laboratory product studies.

The β -hydroxy-peroxy radical (3) can rearrange to form a peroxide-bridged bicyclic radical (9), which further adds O_2 to form a bicyclic peroxy radical. This reaction sequence is currently considered the major fate of β -hydroxy-peroxy radicals. In Figure 5, the peroxide-bridged bicyclic radical (9) reaction step leading to the oxy radical (10) involves the intermediateness of a bicyclic peroxy radical which reacts further with NO to form the oxy radical (10). Other reactions of the bicyclic peroxy radicals are possible and these are discussed below and shown schematically in Figure 6 for the bicyclic peroxy radical formed in the OH-initiated oxidation of toluene. Using a turbulent flow chemical ionization mass spectrometry technique the bicyclic peroxy radicals have now been detected and positively identified for a number of aromatic hydrocarbons and their reactions investigated under different NO_x conditions.

In the atmosphere reaction of the bicyclic peroxy radicals with NO to produce oxy radicals (10) will dominate. The major fate of these oxy radicals will be ring opening, as depicted in Figures 5 and 6, leading to monounsaturated dicarbonyls and α -dicarbonyls. The reaction of dienedials (such as (8) in Figure 5) with OH radicals is another possible route to 1,2-dicarbonyls and unsaturated dicarbonyl products; however, this route will be very minor, if not negligible, under atmospheric conditions.

Another option for the β -hydroxy-peroxy radical, (3) in Figure 5, is rearrangement to an epoxy-oxy radical (13), which can form either the unsaturated epoxy-ketone (14) or/and the ring-opened unsaturated epoxy dicarbonyl product (15). However, the epoxy-carbonyl species have only been observed in a few studies and there is still a lot of uncertainty as to the importance of this reaction route. Despite the uncertainty the channel is often included in aromatic oxidation schemes used in models to ensure carbon mass balance.

In recent years several new investigations, using mainly mass spectrometric techniques, have been reported that have attempted to address the question whether other important chemical processes are missing from the currently formulated aromatic hydrocarbon OH-radical initiated oxidation mechanisms. The results from these investigations support that apart from reactions of the bicyclic peroxy radicals with NO to form α -dicarbonyl and monounsaturated dicarbonyl products, products such as bicyclic nitrates, bicyclic peroxides, bicyclic carbonyls, and bicyclic alcohols (such as shown in Figure 6) may be formed, depending on the $RO_2(HO_2)/NO$ ratio in the experimental system. More investigations using different techniques are needed to verify and quantify these reaction channels.

In recent years, the possibility of ipso addition of the OH radical to alkylated benzenes, i.e., addition of OH at a position occupied by an alkyl substituent followed by ejection of the alkyl group (dealkylation) has been investigated. The process is illustrated in Figure 7 for the reaction of the OH radical with *o*-xylene. Whereas this pathway is known to occur in the liquid phase, it has always been assumed to be negligible in the gas phase with OH preferably adding to a nonsubstituted position.

Figure 4 Possible peroxy radicals generated from OH radical addition to aromatic hydrocarbons taking toluene as an example.

Figure 5 Representation of the various possible reaction pathways postulated to explain the products observed in the OH-radical initiated oxidation of aromatic hydrocarbons using toluene as an example. Only the *ortho* OH-radical addition pathway is shown.

Figure 6 Simplified representation of the possible reactions of a bicyclic peroxy radical formed in the OH-radical initiated oxidation of toluene.

Figure 7 Ipso addition of OH to *o*-xylene followed by demethylation to form *o*-cresol.

However, for a fully substituted aromatic such as hexamethyl benzene OH ipso addition has been shown to be an important gas-phase reaction route. A flow tube study on the OH-initiated oxidation of toluene and the xylenes has reported yields of demethylated phenolic type compounds of between 5 and 10%, however, in an environmental chamber study of *m*-xylene and *p*-cymene an upper limit of 1% was reported for the dealkylation pathway. Therefore, it remains unclear whether the dealkylation pathway is a significant gas-phase oxidation pathway for moderately substituted and alkyl substituted aromatic compounds. However, with increasing degree in alkyl substitution evidence for this pathway should be searched for in experimental product investigations.

Product Yields

In this section, the typical products of the OH-initiated oxidation of aromatic hydrocarbons are discussed. A large number of product studies of the OH-initiated oxidation of aromatic hydrocarbons have been reported. Though many of these studies have focused on toluene, the most abundant aromatic hydrocarbon found in polluted air, numerous data exist for many other aromatic hydrocarbons, including some polycyclic aromatics. A large number of ring-opening products have been observed in the OH-initiated oxidation of aromatic hydrocarbons, but only some of these have been determined quantitatively. Table 5 shows the types of ring-retaining and ring-opening products identified and quantified in the OH-radical initiated oxidation of aromatic hydrocarbons taking toluene as example. Yields are not given, since these can vary quite substantially with the experimental conditions employed. Hydroxybenzenes (e.g., phenol from benzene and cresols from toluene) are major ring-retaining products formed by abstraction of a ring H atom with O₂ (Figure 5), with yields typically of around 60% for phenol from benzene, and 20% for

the cresols from toluene, and rank among the best-quantified products.

All of the possible monounsaturated dicarbonyls and α -dicarbonyls that can be formed in the OH-initiated oxidation of benzene, toluene, and the xylene and trimethylbenzene isomers have now been detected and quantified. All the current aromatic hydrocarbon OH oxidation mechanisms predict a 1:1 stoichiometric relationship between 1,2-dicarbonyl products (such as glyoxal (12) in Figure 5) and unsaturated dicarbonyl products (such as butenedial (11) in Figure 5). Some investigations, however, have found that the unsaturated dicarbonyl products are often observed in significantly lower yields than the 1,2-dicarbonyls, their presumed product partners. However, many of the unsaturated dicarbonyl products are highly reactive and it is thought that secondary chemistry is responsible for the nonstoichiometric product yields. Many of the multitude of reported products observed in low yield are secondary or tertiary in nature, being formed by the further oxidation of stable (nonradical) intermediates of the atmospheric oxidation of the parent aromatic hydrocarbons.

One problem encountered in all existing product studies of the OH-initiated oxidation of aromatic hydrocarbons is the deficient carbon balance. Generally, only between 50 and 60% of the carbon, which reacts with OH radicals is identified as products. The main reason for this is that all the proposed and identified products of the oxidation are highly reactive themselves; most of the products, react about one order of magnitude faster with OH radicals than with the parent aromatic hydrocarbon. This often results, as stated above, in low yields of these products, which makes them difficult to detect and even more difficult to quantify. Such large differences in the reactivity between products and reactants are not observed in any other class of VOCs present in the atmosphere. The high reactivity of aromatic hydrocarbon photo-oxidation products can be explained by the three 'double bonds' in the benzene ring. In the aromatic benzene ring, these 'double bonds' are fully conjugated and consequently very stable. Once the aromaticity is destroyed, however, nonaromatic double bonds are formed, making the products highly reactive.

Table 5 Types of products quantified in the OH-radical initiated oxidation of aromatic hydrocarbons: example for toluene

Uses of Aromatic Hydrocarbon Oxidation Mechanisms and Limitations

Chemical oxidation mechanisms of VOCs are required for air quality simulation models, which are used to predict the formation of secondary pollutants such as ozone and also secondary aerosol formation. Due to computing limitations the model generally uses lumped species or highly

parameterized mechanisms and it is known that the mechanisms, in particular for aromatic hydrocarbons, are not fit for purpose in many respects. One way to obtain a simplified or lumped mechanism that is to use an explicit mechanism which can be systematically reduced such. The explicit mechanism has of course to be fit for purpose for the task to which it will be applied. The most explicit mechanisms for aromatic hydrocarbons are those contained in the Master Chemical Mechanism (MCM), which is maintained by the University of Leeds, UK (MCM: <http://mcm.leeds.ac.uk/MCM/>). The mechanisms have been largely developed from experimental kinetic and product data and are frequently updated to incorporate mechanistic new findings. The mechanisms are designed to provide an explicit representation of the initial OH reaction step for aromatics, as well as all subsequent reactions believed to play a role in the ultimate effect of aromatic oxidation chemistry on air quality.

The MCM aromatic oxidation mechanisms have been tested against environmental chamber experiments in which atmospheric conditions were simulated as closely as possible. Unfortunately, the MCM mechanisms fail to correctly predict ozone production rates, as well as OH radical levels. In the case of toluene, the MCM overpredicts the ozone concentrations by ~55% and underpredicts the OH radical production by ~44%. The simulation experiments highlight that some fundamental aspects of the oxidation mechanisms of aromatic hydrocarbons are not yet fully understood and that further improvement in the MCM are required before it can reliably be used to understand and reduce air quality problems related to elevated levels of aromatic compounds in the atmosphere.

Aerosol Formation from the Oxidation of Aromatic Hydrocarbons

Epidemiological studies have reported an association between daily mortality and fine particles. There are two general classes of PM: primary and secondary. Carbonaceous (organic) aerosol constitutes 20–90% of all submicron particles in the atmosphere, and up to 80% of this is classified as SOA generated in the photochemical oxidation of organic compounds present in the atmosphere. Air-quality models currently underpredict the concentrations of organic aerosol in the atmosphere, especially in the summer and in urban areas showing that our understanding of anthropogenic SOA formation is incomplete.

The fraction of atmospheric SOA originating from the oxidation of the aromatic hydrocarbons is not known with certainty; however, it has been concluded from field and laboratory observations that aromatic hydrocarbons probably play a significant and possibly domineering role in the formation of SOA in urban areas. Toluene (methylbenzene) and other light aromatics are thought to be the dominant anthropogenic SOA precursors. The emissions of toluene in the United States are approximately 1 teragram of carbon per year, and in addition to being an important SOA precursor itself, toluene is often used as a model system representative of the SOA formation from other aromatic VOCs.

Studies of SOA formation from VOCs are typically performed in large, Teflon film reactors (often referred to as smog or environmental chambers). Performing SOA formation experiments in chambers have, however, inherent difficulties

since gas-particle-wall partitioning can occur which can affect both the yield and the chemical composition of the SOA. Recent investigations suggest that wall processing of the SOA may be more of a problem than previously thought. The aerosol mass yields from the photooxidation of aromatic hydrocarbons reported in the literature vary widely and direct comparisons are difficult since, apart from potential wall complications, the experiments are conducted under different conditions and with different aerosol mass loadings which are now known to lead to differences in the measured aerosol yields. It is also still an open question as to whether the aerosol yields observed in laboratory experiments are directly transferable to atmospheric conditions.

Recent laboratory SOA formation yield measurements coupled to gas-phase yield measurements, indicate that approximately 20% of the SOA of benzene, toluene, and *m*-xylene can be ascribed to the secondary reactions of phenolic primary products. The yields for aromatic hydrocarbons as for other VOCs have been shown to be highly sensitive to the NO_x levels, with higher SOA yields being observed under low-NO_x conditions. This dependence of the SOA formation on the NO_x level has been proposed to be the result of differences in concentrations of different oxidants (OH, O₃, and NO₃) or in changes in the peroxy radical chemistry. At high RO₂(HO₂)/NO ratios peroxy-peroxy radical reactions will dominate the fate of the peroxy radicals rather than reaction with NO leading to products more susceptible to SOA formation such as organic hydroperoxides (ROOH). Measurements in studies performed under high-NO_x conditions suggest there may also be a 'rate effect' in SOA formation, in which SOA yields are higher when the oxidation rate is faster. The NO_x dependence of SOA yields is thus a crucial parameter for atmospheric modeling, which is currently very poorly understood. Other parameters, which play a role in determining the SOA yield from aromatics are relative humidity, the presence or absence of seed aerosols, and temperature.

There have been very few studies on the molecular composition of the SOA from aromatic hydrocarbons. Studies to date indicate, i.e., the reactions of ring-opened first-generation products, which are probably responsible for a large fraction of the aerosol formation observed in the photooxidation of aromatic compounds. The chemical nature of only a small fraction (15–30%) of the secondary aerosol mass has been identified to date. It is thought that organic acids formed from the oxidation of α,ω -dialdehydes initially to α,ω -oxyacids and further to α,ω -diacids may be important unidentified components of the aerosol. Evidence has now been found for the presence of bicyclic hydroperoxides in aromatic SOA. Since the organic compounds present in the aerosols have obviously a low vapor pressure, and many are not commercially available, there are considerable experimental hurdles with regard to collection, identification, and quantification, which still need to be overcome before a full aerosol composition specification will be possible.

The formation of SOA from the gas-phase oxidation of aromatic compounds discussed here refers to that which would take place in the first few hours after emission. In the atmosphere, however, SOA will continue to evolve chemically over its atmospheric lifetime of typically 5–12 days. Simulating chemical aging over an extended period of time in laboratory

investigations of SOA formation is a major experimental challenge. At the time of writing, procedures for studying SOA aging in laboratory chambers are in the early stages of development.

Outlook

Although much new and encouraging information concerning the mechanisms of the atmospheric oxidation of aromatic hydrocarbons has emerged in recent years, in particular from mass spectrometric techniques, vital information concerning the actual nature of the ring-opening process which is necessary for realistic model construction is still uncertain. The wealth of new kinetic and mechanistic information obtained, however, allows limits to be put upon some of the various possible ring-cleavage reaction channels. Since the database has been considerably broadened, it is likely that in the near future, with some further refinements in the database, it will be possible to obtain a reasonably accurate description for the photooxidation of aromatic hydrocarbons. This may be achieved either by an experimental breakthrough or by optimization of a 'multi-channel' reaction mechanism (utilizing new kinetic and mechanistic data) to fit a set of well-defined simulation experiments suitable for different atmospheric conditions.

Biogenic Hydrocarbons

A Guenther, Pacific Northwest National Laboratory, Richland, WA, USA

Synopsis

All living organisms produce volatile organic compounds (VOCs) including some that are emitted into the atmosphere where they have a significant impact on the chemical composition of the atmosphere including constituents, such as organic aerosol and ozone, that influence climate. These emissions respond to climate and land cover change, and there may be complex interactions with important climate change implications. Many VOCs are found in living organisms but relatively few are emitted at substantial rates, primarily from vegetation foliage. These include terpenoids (e.g., isoprene), hydrocarbons (e.g., ethene), and oxygenated VOCs (e.g. methanol). Some biogenic VOC emissions also have important ecological roles.

Introduction

All living organisms produce hydrocarbons, which consist solely of hydrogen and carbon, and other volatile organic compounds (VOCs) that can also contain elements such as oxygen, nitrogen, or sulfur. The term VOC will refer here to all VOCs other than methane. The major categories of VOC chemical species (terpenoid, oxygenated, and other) and the important sources (vegetation foliage) are described, and the atmospheric and ecological factors that control the various types of emissions are discussed. Most of the VOCs emitted into the atmosphere are of biogenic (produced and emitted by biological organisms) origin. The remainder, primarily from wood and fossil fuel combustion, is a small fraction of the global total but greatly dominates in urban and industrial areas and in remote areas where biomass burning occurs. The known and suspected ecological and physiological roles of biogenic VOC are noted and their impact on the environment is considered. Biogenic VOCs can have a significant impact on the chemical composition of the atmosphere and are strongly influenced by environmental conditions. As a result, it is likely that global emissions of these compounds will change in response to global climate and land cover change. This raises the potential for a feedback coupling that could significantly perturb the Earth system.

Compounds

Tens of thousands of organic compounds have been identified in plant tissues and more are discovered every year. Many of these compounds have very low volatility, which prevents or greatly limits their emission to the atmosphere. In addition, some organic compounds are stored in plant structures that present substantial barriers to emission to the atmosphere. As a result, a relatively small number of all organic compounds found within plants are emitted at rates that can significantly influence the atmosphere.

Terpenoid VOCs

The terpenoids are an important class of organic compounds that include hemiterpenes (containing 5 carbon atoms), monoterpenes (10 carbon atoms), sesquiterpenes (15 carbon atoms), and diterpenes (20 carbon atoms). Only two

hemiterpenes, isoprene and methyl butenol, are known to be emitted in significant quantities. Isoprene has the single largest contribution to the total global VOC emission. There are about a thousand monoterpene compounds but only less than 20 are emitted into the atmosphere at significant rates. The largest contributor to the global monoterpene emission is α -pinene. Other monoterpenes that are commonly observed as plant emissions include β -pinene, Δ^3 -carene, D-limonene, camphene, ocimene, myrcene, sabinene, β -phellandrene, and p-cymene. Relatively little is known about the emission of the approximately 3000 sesquiterpene compounds found in plants. Their emission is a relatively small component of global biogenic VOCs but may be important for aerosol production. None of the approximately 2000 diterpenes are known to be emitted into the atmosphere in significant amounts but this may be due to a lack of observations targeting these compounds.

Oxygenated VOCs

Biogenic VOCs include a large variety of oxygenated compounds including alcohols (e.g., methanol), aldehydes (e.g., acetaldehyde), ketones (e.g., acetone), acids (e.g., formic acid), ethers (e.g., 1,8 cineole), and esters (hexenyl acetate). The molecular weights of these compounds range from less than 32 g mol^{-1} (e.g., methanol and formaldehyde) to over 100 g mol^{-1} (e.g., decanal and methyl heptenone). The larger compounds are more likely to contribute to aerosol formation or growth. Methanol, ethanol, acetone, and acetaldehyde are thought to be the oxygenated VOCs with the highest global emission rates and have a significant impact on the chemical composition of the atmosphere. There are not enough information to determine whether there are substantial emissions of many oxygenated VOC species.

Other VOCs

There are a number of other organic compounds including alkanes (e.g., ethane), alkenes (e.g., ethene), arenes (e.g., toluene), sulfur compounds (e.g., dimethyl sulfide), and nitrogen compounds (e.g., hydrogen cyanide). Of these compounds, ethene has the highest global emission rate. Some of the other compounds are rarely emitted but emissions can be high for certain conditions and locations. Dimethyl sulfide is a volatile organic sulfur compound that is produced and

emitted by terrestrial vegetation and marine phytoplankton at rates that can have a significant impact on the chemistry of remote atmospheres.

Sources and Driving Variables

Vegetation is the major source of VOC emission into the atmosphere. These emissions are primarily from foliage (leaves and needles). The remainder is from other live tissues including stem, cortical, root, and reproductive tissues. Trees are the major source of global emissions although shrubs and nonwoody plants are important sources of at least some compounds. Microorganisms and animals are a minor source of biogenic VOC emission. Isoprene and acetone are the dominant VOCs emitted in human breath.

VOC Production and Emission Pathways

There are many different biogenic VOC production/emission sources including chloroplasts, specialized defense, unspecialized defense, metabolic by-products, decaying and drying vegetation, plant growth hormones, and floral scents. Each pathway is responsible for the emission of more than one type of VOCs and some VOCs are emitted by more than one pathway.

Chloroplast emissions dominate the global VOC flux. Even though only 30% of all plant species exhibit this type of emission, the emission rates are typically much higher than those of other emission processes. Isoprene is the major chloroplast emission from most landscapes, but some regions are dominated by chloroplast emissions of methyl butenol or monoterpenes (e.g., α -pinene). Isoprene is produced in chloroplasts by a unique enzyme, isoprene synthase, and depends on the availability of photosynthetic carbon, but is distinct from photorespiration. Isoprene penetrates the intercellular space of the leaf and then exits the plant via the stomata. Isoprene synthase activity is controlled primarily by leaf temperature and light (photosynthetically active radiation). Diurnal variations range over several orders of magnitude and are near zero in the dark. The temperature and light conditions that a leaf has been exposed to during the previous hours to days can significantly influence emissions. Leaf age, phenology, nutrient levels, carbon dioxide concentration, and water stress are other factors that control isoprene emission.

Many plants produce and store terpenoid compounds within specialized tissues that act as a physical barrier to insects and pathogens and/or as a feeding deterrent if consumed. These compounds are primarily monoterpenes (C_{10}) and diterpenoids (C_{20}) with a large number, but small quantity, of sesquiterpenes (C_{15}). The biochemistry of these compounds, and the genetic and ecological controls, has been investigated due to the importance of this plant defense mechanism for economically significant plants such as pine trees. Although there are thousands of terpenoids, the total emission from stored terpenoid pools is dominated by contributions from less than 10 compounds. Diurnal variations in emissions of these stored compounds range from about a factor of two to four and are primarily controlled by temperature. The relationship between emission and temperature is exponential and is dependent on the compound and the resistance properties in the plant.

Some of the VOCs produced in unspecialized plant tissues also play a role in defending plants against disease and herbivory. For example, emissions of ethane, ethanol, methyl salicylate, octanone, and methoxyphenol are associated with resistance of plants to herbivore infestations. These compounds can act by repelling pests or attracting predators. The hexenal family compounds (2-hexenal, 3-hexenol, 3-hexenal, 3-hexenyl acetate, hexanal, and hexanol) may have antibiotic properties and can be emitted by damaged plants at very high rates. There is a reasonably good understanding of the mechanisms controlling the production of hexenal family compounds, which are typically triggered by membrane damage due to mechanical wounding or the presence of pathogens.

Ethene is a volatile hormone that controls numerous aspects of plant growth and development, including fruit ripening, seed germination, flowering, and senescence. It can also trigger plant defense and internal concentrations are greatly increased by a variety of stresses. The biochemistry of ethene production is better understood than that of most VOCs but investigations of ethene emission have been primarily directed at understanding its role as a plant hormone and provide little information for numerical emission modeling. Ethene production is widespread in plants and is likely a significant emission from most landscapes. It may be particularly sensitive to changes in ecosystem stress.

Large VOC emissions are observed when vegetation is cut or when dried foliage is hydrated. Thus, the initial cutting of live vegetation as well as long-term emissions from drying and dead vegetation produces significant emissions. The dominant oxygenated VOC emissions include both reactive (e.g., acetaldehyde and hexenal family) and less reactive (e.g., methanol, acetone, and butanone) compounds. These fluxes dominate VOC emissions in agricultural areas during harvesting. Other human activities, including timber harvesting, lawn mowing, and rangeland management practices, may significantly enhance VOC emissions and should be characterized in order to understand the importance and impact of this emission source.

Floral scents are composed of a large variety of VOCs including alkanes, alcohols, esters, aromatics, nitrogen compounds, monoterpenes, and sesquiterpenes. Flowers are likely to be the dominant biogenic source of some of these compounds. Although flowers are expected to be a minor component of annual global VOC emissions, flowering may dominate VOC emissions in some locations at certain times.

At least some portion of the total emission of a number of VOCs (e.g., methanol, formaldehyde, acetone, propene, butene, isoprene, formic, and acetic acid) appears to be emitted by processes other than those described above. These emissions may simply represent the leakage of plant metabolites. For example, methanol can be produced in plants as a result of the enzymatic demethylation of a component of the pectin in plant cell walls. This process is an important step in the elongation process that allows plant cell walls to grow. The biochemical mechanisms for ethanol and acetaldehyde production are also reasonably well understood. Production of these two compounds by plants is expected under anaerobic conditions such as those experienced by roots in flooded soils, wet crevices of damaged trees, and by leaves under certain stressed conditions. Production pathways for acetic acid, acetone, formaldehyde, and formic acid in plant cells have been proposed but need to be confirmed.

Geographical and Seasonal Distributions

The global annual emission of biogenic VOC is estimated to be greater than 1×10^{15} g. Over 99% is emitted by terrestrial vegetation, primarily from foliage. A large fraction of this total is associated with tropical regions due to the high temperature and light regimes, often coupled with a high plant biomass, and emissions that occur throughout the entire year. Regions of higher (northern and southern) latitudes exhibit a pronounced seasonal cycle in the physiological activity of the vegetation resulting in a maximum emission during the summer time when temperature and light intensity are highest. Emission variations are based on environmental, e.g., light and temperature, conditions and land cover characteristics including foliar biomass, and plant species distributions. Emissions from landscapes without vegetation are negligible. For landscapes with vegetation, emissions vary more than the order of magnitude for different locations. Variations of this magnitude are also observed for different seasons at the same location.

Ecological and Physiological Roles

The production of VOC is a significant resource allocation for biological organisms, which leads to the question of why these compounds are lost into the atmosphere. Three possible reasons for biogenic VOC emissions are that they provide a significant benefit to the organism, they represent the loss of an unneeded metabolic by-product, or they are unintentional losses that result from having volatile compounds in a leaky structure. The role of each of these possibilities is discussed below.

Biogenic VOC emissions have an important role in at least some biological organisms. Flowering plants use VOC to attract pollinators. Insects and animals use VOC as pheromones for a variety of signaling activities. Plants can also use VOC to signal other parts of a plant, or even other plants, to begin or end specific growth phases such as flowering. Plants may also use VOC to repel pests, either as an antibiotic or by making the plant less appetizing. The emission of a volatile compound can also be a convenient way of removing a toxic substance produced by an organism. This is particularly useful for an immobile organism that does not have the ability to move away from the waste it has excreted. Examples of potentially toxic compounds that can be removed as VOC emissions include formaldehyde and acetone. Other beneficial roles that have been proposed for biogenic VOC include protecting plants from dangerously high leaf temperatures and modifying the chemical composition of the atmosphere in order to reduce the deposition of toxic compounds, such as ozone, or increase the deposition of needed nutrients, such as some nitrogen compounds.

Biological organisms metabolize organic substrates to produce needed cellular components. These processes often result in the production of metabolic by-products that are not needed by the organism. It is generally expected that organisms have pathways to recycle these by-products into other useful compounds but there may be situations where the organisms simply expel the compound into the atmosphere. The production of some VOCs may protect plants from extreme environmental conditions. This includes protection from high

light intensities, by dissipating excess reducing power, and high temperature, by stabilizing plant membranes.

All organisms exchange gases, e.g., oxygen, water vapor, and carbon dioxide, with their environment. In the process of doing so it is likely that at least some VOCs are unintentionally lost to the atmosphere. In addition to losses through the main gas transport pathways, i.e., the stomata of plants or the mouths of animals, there is the possibility for losses through other structures such as plant cell walls or the skin of animals. These losses would be especially large when a normally airtight structure becomes physically damaged and exposed to the environment. Some plant functions may benefit from having a highly volatile compound that can be moved rapidly to combat stressful situations that arise quickly such as rapidly fluctuating high temperatures or insect infestation. A VOC would be a good candidate for this function but would be susceptible to the unintentional loss of that compound.

Environmental Impact

Atmospheric Chemical Composition

The presence of biogenic VOC in the atmosphere has been recognized for centuries due to the noticeable odor of some of these compounds. For example, hexenol is characteristic of the smell of freshly cut grass and α -pinene contributes to the odor of pine trees. Scientific investigations of biogenic hydrocarbons in the atmosphere were initiated in the Soviet Union in the late 1920s. It was initially thought that these highly flammable compounds might have some military applications. Research in North America began several decades later and was initially focused on the potential role of biogenic hydrocarbons in atmospheric haze. This work continues to be an active area of research due to the recognition that the production of organic aerosol from biogenic VOC may greatly impact the global radiation balance. Of particular interest is the finding that anthropogenic pollution enhances the formation of organic aerosol from biogenic VOC and so contributes to radiative forcing. A major focus for investigations of biogenic VOC during the past four decades has been determining if these compounds have a role in tropospheric ozone formation. This work has demonstrated that a good understanding of biogenic VOC emissions is needed for developing regulatory control strategies for both rural and urban areas in some regions. Other studies have shown that oxygenated VOCs emitted from vegetation contribute to oxidant production in the upper troposphere. It has also been shown that biogenic sources of organic acids, from either primary sources or atmospheric oxidation, can contribute to precipitation acidity.

Carbon Balance

VOC emissions are a minor but significant pathway for the flow of carbon between an ecosystem and the atmosphere in at least some landscapes. Since the fate of most VOCs is oxidation to CO_2 , these CO_2 precursors may need to be considered for an accurate accounting of global CO_2 sources and sinks. The total annual VOC flux of over 1×10^{15} g of carbon is significant in comparison to the estimated annual global atmospheric CO_2 increase of about 3×10^{15} g of carbon. Net CO_2 fluxes between terrestrial

Figure 1 Illustration of a potential global feedback coupling driven by changes in biogenic VOC emissions.

landscapes and the atmosphere at regional scales are estimated using complex models of net ecosystem production, which treat explicitly carbon uptake by photosynthesis and losses through autotrophic and heterotrophic respiration. Some of these models are being developed to treat explicitly carbon losses through VOC emission since they are of similar magnitude, and have similar levels of uncertainty, as other terms that now receive explicit treatment (e.g., cement production).

Global Change and Possible Feedbacks

Biogenic VOC emissions can influence the chemical composition of the atmosphere, including radiatively active constituents that can modify the physical environment resulting in a global warming or cooling. The chemical and physical environment, in turn, can significantly influence the biosphere through nonlinear relationships with the ecological and physiological processes controlling VOC emission. This interaction may thus result in a global feedback coupling involving the chemical and physical climate system and operating over a wide range of time and spatial scales. The major components of this system are illustrated in **Figure 1** and are discussed below.

Interactions between VOC emissions and the global chemical (e.g., ozone, OH, methane, CO₂, NO₂, and RONO₂) environment are complex and nonlinear and therefore difficult to predict. Increases in emissions of some VOCs are likely to result in increases of gases that can increase radiative forcing (leading to warming) while others, such as those that can form organic particles, may decrease radiative forcing (leading to cooling). Due to the large differences in emission rates associated with different vegetation types, there is a substantial potential for land use change to influence biogenic emissions. Since woody plants tend to have much higher isoprene and monoterpene emission rates, compared to crops and grasses, it might be presumed that deforestation would greatly reduce biogenic

VOC emissions. However, there is a tendency for higher isoprene emissions from the woody plants (shrubs and sun tolerant trees) that replace a closed canopy forest. In addition, oxygenated VOC emissions tend to be higher from degraded and deforested landscapes. There is an equally large potential for perturbed biogenic VOC emissions as a result of climate change. Biogenic VOC emissions are very sensitive to temperature and an increase of a few degrees could lead to increase in emissions of more than 25%. The overall result of expected future land use and climate change is an increased biogenic VOC production that could result in significant perturbations in trace gas distributions and global biogeochemical cycles.

Synopsis

This article provides an overview of the chemical composition of clouds and the chemistry occurring within cloud and fog droplets. The processes by which chemical species enter cloud droplets from the gas and aerosol phase are summarized. The most prominent aqueous chemical processes occurring in clouds and fogs are detailed, including sulfur oxidation and complexation, oxidant chemistry, and secondary organic aerosol formation. Some emerging topics like biological materials are introduced. The article closes with a discussion of the role of clouds in atmospheric deposition mechanisms.

Introduction

Clouds occupy a small but important fraction of the total volume of the troposphere. In addition to playing a key role in the global hydrologic cycle and influencing atmospheric radiative transfer, clouds interact with a variety of chemical species. Together with gases and particles, clouds comprise a complex multiphase system. Clouds act both as reactors for the

production of new chemical species and as vectors for particle and trace gas removal, via wet deposition and direct deposition of cloud and fog drops to the surface.

Figure 1 provides an overview of several important processes in the multiphase atmospheric system. Clouds and fogs (clouds in contact with Earth's surface) interact with both aerosol particles and trace gases. The incorporation of particles and gases into cloud drops is the key step in determining the

Figure 1 Schematic representation of the multiphase cloud-particle-trace gas system in the atmosphere. Included are processes of dry and wet deposition, particle and gas scavenging by cloud drops, chemical reaction, and precipitation formation in a mixed phase (ice-liquid water) cloud.

initial chemical composition of the cloud. In the sections below, we discuss several aspects of tropospheric cloud chemistry. While not discussed here, it is important to keep in mind that clouds also occur in the stratosphere where they play an important role in promoting heterogeneous reactions important to stratospheric ozone depletion and other processes.

Cloud Drop Formation

Cloud drops form via condensation of water vapor onto a subset of particles termed as cloud condensation nuclei (CCN), a process known as *heterogeneous nucleation*. In the absence of suitable particles, clouds would not form readily as enormous supersaturations are required for the homogeneous nucleation of water vapor. Many atmospheric aerosol particles are hygroscopic. They can take up or lose water in response to changes in the ambient relative humidity (see **Aerosols: Aerosol–Cloud Interactions and Their Radiative Forcing**). At high humidity these particles can take up water vapor. The point at which a dry salt particle spontaneously takes up water vapor to form a saturated salt solution is known as the relative humidity of deliquescence (RHD). The RHD depends on the salt composition. Not all types of particles exhibit deliquescence. Acidic particles, for example, generally have some water associated with them even at extremely low relative humidities.

Particles containing liquid water are often referred to as haze particles. As the humidity increases, above the RHD for deliquescent salt particles, haze particles take on additional water to maintain equilibrium with the partial pressure of water vapor in the atmosphere. The equilibrium partial pressure of water vapor above a haze drop depends on its size and composition. Increased drop curvature raises the equilibrium water vapor pressure via the Kelvin effect. Increased drop solute content lowers the equilibrium vapor pressure by displacement of water molecules near the drop surface. The combined effects of drop curvature and solute content are often described using Köhler theory (see **Aerosols: Aerosol–Cloud Interactions and Their Radiative Forcing**). Application of Köhler theory indicates that for a given particle size, there is a critical supersaturation above which drops will spontaneously take up water vapor and grow unstably. Such drops have been *activated*. The process of activation is also referred to as nucleation scavenging. Growth of activated drops is limited primarily by the availability of water vapor. Haze particles that do not reach their critical supersaturation will not activate and will remain in equilibrium with the ambient water vapor concentration.

Many types of atmospheric particles are capable of serving as CCN. In some clouds, particles as small as 0.1 μm diameter can activate and grow into cloud drops. In other cases, particularly when supersaturations are low and/or particle concentrations are high, the minimum particle size activated may be 0.5 μm or larger. CCN have traditionally been thought to be comprised mainly of sulfate particles, sea salt particles and, in some environments, nitrate particles. Many studies, however, demonstrate that some carbonaceous particles are also efficient CCN. Substantial research efforts are ongoing to elucidate interactions of carbonaceous particles with clouds and fogs.

The soluble fraction of the CCN determines the initial chemical composition of the cloud drop. In addition to

nucleation scavenging, unactivated (interstitial) aerosol particles can be incorporated into cloud drops by a variety of mechanisms including interception, inertial impaction, and diffusion. While nucleation scavenging can often be quite efficient, scavenging of interstitial particles tends to be relatively inefficient.

The concentration of a compound in the aqueous phase resulting from particle scavenging can be expressed as

$$C_w = \frac{\varepsilon_a c_a}{\text{LWC}} = C_a \frac{(\varepsilon_n + \varepsilon_B + \varepsilon_C)}{\text{LWC}} \quad [1]$$

where C_w is the aqueous phase concentration inside the droplets resulting from particle scavenging, C_a is the initial mass concentration of the particles, and ε_a is the mass fraction incorporated in the drops: the scavenging efficiency. LWC is the cloud's liquid water content. ε_n , ε_B , and ε_C represent the mass fraction of matter incorporated by nucleation (ε_n), Brownian motion (ε_B), and collision (ε_C). Overall mass scavenging efficiencies for soluble aerosol species, such as sulfate or chloride, may be only 20–30% for polluted radiation fogs but can approach 100% for clouds formed by vigorous updrafts in pristine environments. Similar results were recently reported for organic carbon with up to 90% scavenging efficiency for fogs in more remote locations while elemental carbon scavenging efficiencies are typically lower. The scavenging efficiency of organic aerosol particles has been demonstrated to vary depending on the source of particle production and associated organic matter composition.

Dissolution of Soluble Gases

In addition to particle scavenging, the composition of cloud drops can be significantly affected by dissolution of soluble gases. These processes are represented in **Figure 2**, where several key soluble gases are shown. Even in remote areas, cloud drops can be partially acidified by dissolution of carbon dioxide. In polluted areas, further acidification can occur by the uptake of nitric acid and sulfur dioxide. In certain environments hydrochloric acid can also be important. Low molecular weight carboxylic acids, especially formic and acetic acids, can be important contributors to drop acidity in both polluted and pristine environments. Sulfur dioxide is moderately soluble in most cloud drops. Its uptake is of particular interest because of the potential for rapid oxidation to sulfate in the aqueous phase. Gaseous oxidants such as hydrogen peroxide and ozone are important because they serve as effective oxidants of dissolved sulfur dioxide. A number of other organic gases can also dissolve into drops. Dissolution of formaldehyde is depicted in **Figure 2**. Carbonyl species, in particular formaldehyde and atmospherically abundant dicarbonyls such as glyoxal and methylglyoxal, are of interest because they may be present at high concentrations and can react with dissolved sulfur dioxide. The dissolution of volatile organics and their subsequent aqueous phase reactivity can yield nonvolatile material and has recently been suggested as an important mechanism for secondary organic aerosol (SOA) generation.

The extent to which a gas partitions into a cloud drop at equilibrium depends on its solubility. In some cases the time required to achieve equilibrium is long relative to the rate of

Figure 2 Schematic representation of the influence of particles and gases on cloud/fog drop composition. Reactions between several of the dissolved species shown here can also be important.

reaction of the dissolved gas or to the drop's lifetime, so that phase equilibrium may not be achieved. When the liquid and gas phases are in equilibrium, the concentration in the drop is given by Henry's law:

$$[X_{\text{aq}}] = H_X p_X, \quad [2]$$

where $[X_{\text{aq}}]$ is the concentration of the species X in solution ($\text{mol} \cdot \text{l}^{-1}$), p_X is the partial pressure of X in the atmosphere (atm), and H_X the Henry's law constant for X ($\text{mol} \cdot \text{l}^{-1} \cdot \text{atm}^{-1}$). The solubility of most gases increases with decreasing temperature.

As written above, Henry's law expresses the physical solubility of a gas. For many species, the overall solubility is further enhanced by dissociation or reaction in solution. An important example is the dissolution of sulfur dioxide.

If the compounds are reactive in solution, it is useful to define an effective Henry's law constant which takes into account the chemical reactions and includes the total amount of incorporated compound (e.g., $\text{H}_2\text{SO}_3 + \text{HSO}_3^- + \text{SO}_3^{2-}$)

$$H_{\text{SO}_2}^* = \text{H}_{\text{SO}_2} \left(1 + \frac{K_1}{[\text{H}^+]} + \frac{K_1 K_2}{[\text{H}^+]^2} \right) \quad [6]$$

In eqn [6] K_1 and K_2 are the acid dissociation constants corresponding to reactions [4] and [5], respectively. In case of acid-base reactions in solution, the effective Henry's law constant varies with pH. In case of sulfur dioxide dissolution,

the formation of the ionized forms provides extra reservoirs for sulfur dioxide in solution, thereby increasing the effective solubility of sulfur dioxide substantially when the drop pH exceeds one or both pKa's for dissolved sulfur dioxide. In addition to ionization, other reversible processes undergone by dissolving compounds are often considered in determining effective Henry's law constants. A good example is the aqueous hydration of formaldehyde to form a gem diol. The solubility of atmospheric trace gases in aqueous solution varies strongly, from slightly soluble species (e.g., O_3) to moderately soluble species (e.g., SO_2) to highly soluble species (e.g., H_2O_2 and HNO_3).

It is noteworthy that some field and laboratory observations of the partitioning of gases show a substantial sub- or supersaturation of volatile species in the aqueous phase relative to the gas phase. Hence, species distribution between phases does not always achieve equilibrium, at least on atmospherically relevant timescales. Such situations can occur for specific species as a result of mass transfer limitations between phases, high reactivity in the aqueous phase combined with limited rates of uptake from the gas phase, or, potentially, the presence of films on the surface of droplets.

Drop Composition

The combined effects of particle and gas scavenging, along with chemical reactions (discussed below), determine the chemical composition of cloud drops. Absolute concentration levels of individual species are also influenced in part by condensational growth or evaporation of drops. Major species commonly found to dominate fog and cloud composition include a number of ions, especially nitrate,

Figure 3 Average mass composition of bulk fog and cloud water samples. OM represents organic matter, assumed equal to 1.8 times the TOC concentration to represent mass contributions from hydrogen, oxygen, nitrogen, and other atoms in organic molecules. Other ions include H^+ , Mg^{2+} , Ca^{2+} , and K^+ . Polluted fog example is from Fresno (California), remote clouds are from Whistler (Canada), marine clouds are from the North Pacific, and polluted cloud example is from Mt. Tai, China.

sulfate, and ammonium. In coastal regions sea-salt ions are important contributors to the drop composition, while in some locations contributions of soil dust components can be important. Organic matter is also an important component of fog and cloud composition in many environments (Figure 3). In some polluted environments, concentrations of formaldehyde, glyoxal, methylglyoxal, acetate, and formate can reach levels similar to those observed for major inorganic ion species. Table 1 provides approximate concentration ranges of various chemical species observed in clean and polluted clouds and in polluted radiation fogs.

Table 1 Typical range of LWC and solute concentrations in remote and polluted clouds and fogs

Solute	Polluted cloud	Polluted fog	Remote cloud
LWC (g m^{-3})	0.05–1	0.02–0.8	0.05–2
pH	2–5	3–7	4–6
SO_4^{2-} ($\mu\text{eq l}^{-1}$)	50–2000	50–5000	5–50
NO_3^- ($\mu\text{eq l}^{-1}$)	10–2000	50–20 000	0–20
NH_4^+ ($\mu\text{eq l}^{-1}$)	50–1000	100–20 000	10–50
Cl^- ($\mu\text{eq l}^{-1}$)	0–500	0–100	0–500
Na^+ ($\mu\text{eq l}^{-1}$)	0–500	0–200	0–500
HCOO^- ($\mu\text{eq l}^{-1}$)	0–100	0–1000	0–20
CH_3COO^- ($\mu\text{eq l}^{-1}$)	0–100	0–500	0–10
HCHO (μM)	10–50	5–500	0–10
CHOCHO (μM)	5–50	5–200	0–10
TOC (ppmC)	2–30	5–50	0–8
Fe (μM)	0.01–10	1–50	0–5

Experimental observations reveal that only a fraction of the total organic carbon (TOC) content of fogs or cloud is comprised of low molecular weight compounds such as formate, acetate, formaldehyde, and other small carbonyls and dicarbonyls. Some efforts have been made to comprehensively characterize the higher molecular weight compounds in fogs and clouds. Initial studies revealed similarities to humic substances, although evidence shows that the higher molecular weight species in fogs and clouds only present limited similarities to terrestrial humic substances. Other fractions appear similar to fulvic acids or unique to atmospheric materials. The current consensus might be summarized as follows: organic matter is complex, comprised of thousands of species, many of them in the range of hundred to several hundred Dalton molecular weight with a high content of heteroatoms (O,N,S). Many studies have focused on measuring particular compound families because of their specific sources or their toxicity. Hundreds of organic compounds have been identified in fogs and clouds in recent years using advanced mass spectrometric analysis. Organic compounds measured in fogs and clouds include carboxylic acids (formic, acetic, pyruvic, propionic), aldehydes (formaldehyde, acetaldehyde, glyoxal, methylglyoxal, benzaldehyde), polycyclic aromatic hydrocarbons (chrysene, pyrene, fluoranthene, benzo(e)-pyrene, benzo(b)-fluoranthene), ketones (acetone), carbohydrates (levoglucosan, mannosan, galactosan), pesticides (carabryl, diazinon, malathion, lindane, atrazine), and various phenols (phenol, 2- and 4-nitrophenol, 2,4-dinitrophenol, methyl nitrocatechol, *m/p*-cresol, guaiacol, syringol). This list of compounds is illustrative but not exhaustive. Many organic compounds found in cloud drops are emitted during combustion while others are formed

as secondary products of atmospheric reactions. With the exception of the low molecular weight carboxylic acids and aldehydes, as well as levoglucosan in a strongly biomass burning impacted environment, cloud drop concentrations of most individual organic compounds are typically much smaller than those of the major inorganic species.

It is noteworthy that a part of the organic matter in clouds is of biological origin including amino acids, proteins, and other cellular materials, including RNA and DNA. There is substantial evidence for the presence of whole biological organisms (bacteria, virus, fungi) as well as spores in fogs and clouds (see **Tropospheric Chemistry and Composition: Aerosols/Particles**). The variability of organisms, their viability, their contribution to cloud organic matter, and the potential impact of biological reactions on cloud chemistry are currently under investigation.

Although clouds have traditionally been assumed to be comprised of populations of chemically homogeneous drops, there is now substantial evidence that a wide variety of drop compositions often exists within a given cloud or fog. These differences arise in part from the variability in the composition of the underlying CCN. Other differences arise from variations in condensational growth rates as a function of drop size and from nonequilibrium absorption of highly soluble trace gases. Increasingly, cloud chemistry models and measurements are being designed to account for the chemical heterogeneity among cloud drop populations. This heterogeneity can affect rates of in-cloud reactions as well as the efficiency of solute deposition through precipitation scavenging and direct cloud drop deposition.

Reactions Occurring in Cloud Drops

Many chemical species incorporated in cloud drops can react in the aqueous phase. Considerable attention has been focused on the aqueous oxidation of dissolved sulfur dioxide to sulfate, although numerous other reactions have also been shown to be important, including the formation of SOA. Several key chemical reactions are briefly discussed in the following.

Aqueous Phase Sulfur Oxidation and Complexation

Oxidation of SO_2 to H_2SO_4 is a key reaction in the atmosphere. The resulting sulfate contributes to acid deposition, visibility degradation, respiratory problems, and climate modification. Sulfate production occurs both in the gas phase and in the aqueous phase, but the latter is much faster.

As described above, dissolution of SO_2 in cloud drops is a function of drop pH (Figure 4). In the pH range usually encountered in cloud and fog drops (pH between 2 and 7), the dominant form of dissolved sulfur dioxide is bisulfite. As the pH climbs above 7, the speciation shifts toward sulfite.

Several S(IV) oxidation mechanisms occur in the aqueous phase; their relative importance depends on the drop pH and the availability of oxidants and catalysts. Three important aqueous S(IV) oxidation pathways are oxidation by hydrogen peroxide, ozone, and oxygen (autooxidation) catalyzed by Fe(III) and Mn(II). Figure 5 depicts the rate of sulfate production by these three pathways for 1-ppbv sulfur dioxide in the

Figure 4 The speciation of dissolved sulfur dioxide as a function of pH.

Figure 5 The pH dependence of the rate of aqueous S(IV) oxidation by hydrogen peroxide, ozone, and oxygen (catalyzed by Fe(III) and Mn(II)). Conditions represented in the figure are $T = 298 \text{ K}$, $p_{\text{SO}_2} = 1 \text{ ppbv}$, $p_{\text{O}_3} = 30 \text{ ppbv}$, $p_{\text{H}_2\text{O}_2} = 1 \text{ ppbv}$, $\text{Fe(III)} = 2.5 \times 10^{-6} \text{ M}$, and $\text{Mn(II)} = 1.0 \times 10^{-6} \text{ M}$.

presence of 30-ppbv ozone and 1-ppbv hydrogen peroxide. The rate of production is shown as a function of drop pH.

In many clouds hydrogen peroxide is assumed to be the dominant S(IV) oxidant. As shown in Figure 5, this oxidation pathway tends to be much faster than the others at lower pH values. While the ozone and autooxidation paths become slower with decreasing pH, the rate of the hydrogen peroxide pathway is essentially independent of pH over the range of interest. The lack of pH dependence results from the opposing pH dependence of two contributing factors. While the effective solubility of sulfur dioxide decreases with decreasing pH, the intrinsic rate of sulfate production increases at lower pH. It is believed that oxidation occurs by nucleophilic displacement of a water molecule by hydrogen peroxide attack on bisulfite

followed by reaction of the peroxymonosulfurous acid intermediate with hydrogen ion to yield sulfuric acid

Because the second step is rate limiting, the intrinsic rate of oxidation increases with increasing hydrogen ion concentration. Oxidation of S(IV) is also possible by organic peroxides, but those reactions are of lesser importance due to their lower atmospheric concentrations and their lower aqueous solubility.

At higher pH, or after available hydrogen peroxide has been consumed, S(IV) oxidation by ozone can be important. The rate of reaction of S(IV) with ozone in aqueous solution can be expressed as

$$-\text{d}[\text{S(IV)}]/\text{d}t = (k_0\alpha_0 + k_1\alpha_1 + k_2\alpha_2)[\text{S(IV)}][\text{O}_3] \quad [9]$$

where k_0 , k_1 , and k_2 are the reaction rate constants for reaction of ozone with H_2SO_3 , HSO_3^- , and SO_3^{2-} , respectively; α_0 , α_1 , and α_2 represent the fractions of dissolved sulfur dioxide present as H_2SO_3 , HSO_3^- , and SO_3^{2-} , respectively. Because the effective solubility of sulfur dioxide increases with pH and because sulfite is oxidized much more rapidly than bisulfite, which is oxidized more rapidly than sulfurous acid, the rate of sulfate production by this pathway increases strongly with increasing pH. As shown in Figure 5, the rate of this pathway can exceed even that of the hydrogen peroxide pathway at pH values greater than 5 for typical conditions. The rate of this pathway becomes so rapid, in fact, that it tends to become mass transport limited for larger drops at high pH. This is especially likely when formaldehyde is present as a copollutant, since dissolved sulfur dioxide is rapidly consumed by reaction with both ozone and formaldehyde at high pH.

Aqueous S(IV) oxidation by oxygen is also possible but is very slow in the absence of catalysts. The reaction can be fast enough to be important when catalyzed by certain trace metals including Fe(III) and Mn(II). Of particular interest is the synergistic catalysis afforded by the simultaneous presence of Fe(III) and Mn(II). While several investigators have reported oxidation rate expressions for this pathway, there is far from uniform agreement among the reported expressions. Evaluation of the importance of this pathway in actual clouds and fogs is further complicated by the difficulty of making accurate measurements of iron and manganese speciation in the field.

In some circumstances, S(IV) oxidation by radicals, including OH, Cl_2^- , and Br_2^- , may also be important, especially in polluted conditions where the pH is low and sulfur dioxide concentration far exceeds the hydrogen peroxide concentration.

Field studies have found S(IV) to be present in cloud droplets at much higher concentrations than predicted by Henry's law, even accounting for ionization of dissolved sulfur dioxide in solution. An important reason accounting for this apparent discrepancy is the tendency for sulfite and bisulfite to form complexes with various aldehydes, especially formaldehyde:

The product of the reaction with formaldehyde is hydroxymethanesulfonate (HMS). Formation of HMS is favored at high pH. Significant concentrations of HMS have been measured in high pH fogs in polluted environments, including California's San Joaquin Valley. Formation of HMS is of interest because it represents an additional sink for sulfur dioxide in high pH drops and because it is fast enough under those conditions to limit the amount of aqueous phase sulfate production. Although S(IV) complexation by other aldehydes can also occur, these reactions are generally of lesser importance than those with formaldehyde due to the lower solubilities of higher molecular weight aldehydes and their lower concentrations in the atmosphere. HMS is stable with respect to oxidation by O_3 and H_2O_2 , but may be oxidized by OH.

Oxidant Chemistry

A number of other reactions also occur in cloud drops involving radicals and other oxidants. Several oxidants, including H_2O_2 , O_3 , HO_2 radicals, and OH radicals, contribute importantly to aqueous phase atmospheric chemistry. Organic peroxides and organic peroxy radicals do not play an important role because of their lower atmospheric concentrations and/or lower aqueous solubilities.

H_2O_2 , O_3 , HO_2 , and OH can all be transferred to cloud or fog drops from the gas phase. H_2O_2 , HO_2 , and OH can also be generated photolytically in solution. Several photolytic sources exist for OH production, including photodissociation of H_2O_2 , iron-hydroxocomplexes, nitrate, and nitrite. OH can also be produced by the photo-Fenton reaction

where L denotes an organic ligand such as oxalate. Experimental studies confirm that HO_2 is formed photochemically upon the illumination of cloud and fog samples, subsequently yielding H_2O_2 . Superoxide (O_2^-) is believed to be formed from reaction of Fe(II)-oxalate complexes

followed by protonation to yield HO_2 .

Superoxide can form peroxide in solution via

Fe(II) has also been postulated to react with HO_2 (or O_2^-) to form H_2O_2

Overall, the redox pair of Fe(II)/Fe(III) catalyzes the degradation of oxalate into CO_2 and H_2O_2 .

Laboratory studies of the effect of sunlight illumination on cloud samples suggest that these reactions can be important in both producing H_2O_2 and influencing the daytime cloud pH.

OH and HO₂ can also be formed in solution as a result of bimolecular reactions and radical interconversion processes. One reaction of particular interest is the oxidation of hydrated formaldehyde (methylene glycol) by OH to produce HO₂ and formic acid. The overall stoichiometry for this multistep reaction is

Formic acid is commonly observed in clouds and fogs formed in both pristine and polluted environments. Similar reactions are possible for oxidation of hydrated formaldehyde by other radicals, including NO₃, SO₄⁻, Cl₂⁻, and CO₃⁻. Unlike the radicals discussed above, which can be formed *in situ* or transferred from the gas phase, SO₄⁻, Cl₂⁻, and CO₃⁻ are only formed in the aqueous phase.

Formic acid and other higher molecular weight organic acids are also subject to oxidation by aqueous radicals. Reaction between formic acid and OH,

represents an efficient source of HO₂ and a strong sink for OH. OH is also capable of oxidizing formate anion, so that HO₂ formation by formic acid oxidation is not expected to vary strongly with pH.

In addition to reacting with aldehydes and organic acids, aqueous phase radicals are capable of reacting with other organic substrates containing abstractable hydrogen atoms. Because we know relatively little about the organic speciation of fog and cloud drops, it is difficult to predict accurately how such reactions might impact the lifetimes of aqueous phase radicals.

Several aqueous radicals are believed to undergo reaction with one or more transition metals. In addition to reaction with iron, reactions are also possible with manganese, cobalt, and copper. Copper is of particular interest because it reacts quick enough with HO₂/O₂⁻ to compensate for its generally low concentrations in atmospheric waters, while manganese and cobalt are not expected to significantly influence aqueous phase radical concentrations.

Reactions with nitrite may also represent important sinks for aqueous radicals including OH. The mechanism for the reaction of radical species X with nitrite is given by

Cloud drop scavenging of HO₂ from the gas phase and *in situ* HO₂ production via the mechanisms discussed above have received attention because of their potential effects on tropospheric ozone concentrations. One expects that depletion of HO₂ from the gas phase should influence ozone concentrations in the gas phase because of the suppression of the reaction:

Further, dissociation of HO₂ in solution to form superoxide can promote ozone destruction in the aqueous phase via

The overall effect of clouds on tropospheric O₃ concentrations remains a topic of discussion with some authors arguing for a potentially significant effect while others suggest it is probably not a major factor. Differing conclusions stem at least in part from differences in the reaction mechanisms considered.

Formation of Secondary Organic Aerosol Material

In recent years laboratory and fieldwork have provided substantial evidence that fogs and clouds can convert volatile organic gases into nonvolatile compounds via aqueous phase reactions and, hence, contribute to the formation of SOA. The number of precursor compounds and chemical processes considered important for SOA formation is ever increasing. We will discuss here the most studied molecular systems involving glyoxal and methylglyoxal, two species formed in the gas phase from biogenic and anthropogenic precursors (*see Aerosols: Aerosol Physics and Chemistry*). The SOA contributions from aqueous phase reaction of these species are likely to be especially important as they are some of the most abundant individual organic compounds in fogs and clouds as detailed earlier.

SOA formation processes can be separated into photochemical processes and *dark* (nonphotochemical) reactions. In the dark reactions, oligomerization of dicarbonyls with themselves or other species like amines is observed. Oligomers are small polymers containing only a few monomer units. The resulting daughter species have higher molecular weight than the precursor molecules and are considerably less volatile. These processes are sensitive to the precursor concentrations and hence are particularly prominent in highly concentrated solutions like haze droplets and are considered of lesser importance in more dilute (grown) cloud and fog water droplets.

In photochemical processes, the volatile precursors are oxidized to less volatile species. In the case of glyoxal, for example, glyoxal might be oxidized into glyoxilic acid and further into oxalic acid.

Photochemical experiments reveal a multitude of products, indicative of various simultaneous pathways. In addition photochemical experiments also show the formation of oligomers similar to those produced in dark reactions.

Deposition

The chemical and microphysical properties of clouds exert a significant influence on the composition of precipitation and the resulting wet deposition. Precipitation (rain drops and snow crystals) can form in a variety of ways. Outside the tropics, much precipitation is produced in mixed phase (ice-liquid water) clouds. In this environment precipitation is formed in the ice phase in the presence of supercooled cloud drops. Ice crystal growth can occur by water vapor deposition, inertial capture of cloud drops (*accretion* or *riming*), and ice crystal aggregation. Because the saturation vapor pressure of

water is higher over liquid water than over ice at the same temperature, ice crystals often take up water vapor at the expense of the cloud drops. As the cloud drops evaporate, their solute concentrations increase. Meanwhile, the condensation of water vapor on the ice crystal surface tends to dilute the concentrations of those species present. Consequently, it is common for precipitation to possess much lower solute concentrations than found in collocated cloud drops. For larger ice crystals and larger cloud drops, accretional growth of precipitation becomes more important. When crystals are heavily rimed, their composition has been shown to closely resemble that of the accreted cloud drops. Because accretional growth favors inertial capture of larger cloud drops, any drop size-dependence of cloud drop composition can influence the precipitation scavenging efficiencies of individual solute species. This is also true in warm rain formation, where collision and coalescence of large cloud drops leads to formation of rain drops.

In some environments, cloud and fog drops can be directly deposited on Earth's surface. Drops are removed by inertial impaction, interception, and sedimentation. The latter process dominates removal in radiation fogs while the former processes can be quite important for capture of cloud drops by montane forest canopies. Various studies in the United States and Europe have shown that for high elevation sites with a high cloud interception frequency, hydrologic input by direct cloud deposition is measurable but often low compared to the input by rain and snow. However, because cloud solute contents are often far higher than precipitation solute contents, cloud drop deposition can significantly enhance total wet deposition fluxes of many chemical species from the atmosphere to terrestrial ecosystems. Likewise, studies of radiation fogs reveal that they can represent an important vector for deposition of accumulation mode aerosol particles in polluted environments.

In certain parts of the world, including coastal northern California and parts of the Hawaiian Islands, the hydrologic input from cloud drop deposition appears to be an important contributor to the survival of some plant species. Likewise, cloud drop deposition has been harnessed in some arid regions as a means of supplementing the local water supply for small towns and villages. Large mesh screens are erected on ridge tops, where nonprecipitating clouds are frequently intercepted, to capture water for domestic use.

Introduction

Molecular hydrogen (H₂) belongs to the group of the five most abundant trace gases in the troposphere. The mean tropospheric mixing ratio is roughly about 500 parts per billion by volume (ppbv), a volume fraction of 500×10^{-9} . In the atmosphere H₂ is also present in two isotopic forms: the stable compound HD (¹H²H) and the radioactive form HT (¹H³H). In contrast to carbon dioxide (CO₂), methane (CH₄), nitrous oxide (N₂O), and carbon monoxide (CO), H₂ is not a greenhouse gas. Scientific interest in its atmospheric distribution and budget has been mainly due to the following aspects.

1. During the nuclear weapons tests in the 1950s, radioactive tritium (³H) was released in the form of HT into the atmosphere in significant amounts. The need for information about possible removal mechanisms other than radioactive decay motivated the first detailed studies of the global budget of molecular hydrogen.
2. In addition to carbon monoxide (CO), H₂ is a major product of the photochemical oxidation of CH₄ and other hydrocarbons in the atmosphere. Therefore, the tropospheric cycles of these three trace gases are strongly coupled and information on the H₂ budget will also improve the knowledge about the tropospheric budget of the other species.
3. In addition to methane (CH₄) and water vapor (H₂O), H₂ contributes to the budget of total water, defined as

$\sum \text{H}_2\text{O} = 2\text{CH}_4 + \text{H}_2\text{O} + \text{H}_2$, in the stratosphere. Because the greenhouse effect of H₂O contributes to the negative forcing (cooling) in the lower stratosphere, and owing to the direct effect of water vapor in heterogeneous reactions that activate reactive chlorine, the temporal evolution of $\sum \text{H}_2\text{O}$ is of some importance for the future development of the stratospheric ozone layer. Therefore, the tropospheric H₂ budget must be understood in order to assess a possible long-term global trend of the H₂ mixing ratio and its contribution to the temporal trend of $\sum \text{H}_2\text{O}$ in the lower stratosphere.

This article summarizes the known information about the spatial and temporal distribution of molecular hydrogen in the troposphere. The most important production and removal terms that contribute to the global tropospheric H₂ budget are reviewed from the current literature.

Global Tropospheric Abundance

The first reliable observation of molecular hydrogen in tropospheric air was made in 1923 by P.M. Schuftan at an air liquefaction plant in Southern Germany. He found a mixing ratio of 500 ± 100 ppbv, which was first reported in the scientific literature by F.A. Paneth in 1937. Until 1980 only few measurements of H₂ in the nonurban atmosphere were available. These are summarized in Figure 1 together with the

Figure 1 Time series of reliable observations of molecular hydrogen in nonurban tropospheric air. The data for the period from 1950 until 1977 are from (a) Ehhalt *et al.* (1977); (b) Schmidt (1974); (c) Schmidt (1978); (d) Heidt and Pollock (1976); (e) Seiler *et al.* (1978); (f) Herr and Barger (1978); and (g) Fabian *et al.* (1978). The data for the period from 1985 until 1997 were taken from the more systematic studies: (h) and (i) Khalil and Rasmussen (1990); (j) Novelli *et al.* (1999); (k) Francey *et al.* (1998); and (l) Simmonds *et al.* (2000). Boxes indicate the variability (vertical scale) and the time period (horizontal scale) of the various observations. Open and shaded boxes represent data for the Northern and Southern Hemispheres, respectively.

results obtained during some more extended series of observations that were made up to 2000.

Apparently, the available historical data set does not indicate any systematic long-term trend of the global H₂ mixing ratio. Two more recent studies have reported a slight increase over observational periods of a few years. However, the study in 1999 by Novelli and colleagues, which includes observations from a large number of globally distributed stations rather indicates a slight decrease of the H₂ mixing ratio of about 3% over the period from 1991 to 1996.

The early data plotted in Figure 1 suggest a larger variability than those obtained after 1980. In large part this is due to the individual absolute calibration scales employed during the different observational series reviewed in 1979 by Schmidt and colleagues. Later data reported by various workers (see Further Reading) indicate more consistent mean mixing ratios. The observed variability is mainly due to the seasonal variation of the H₂ mixing ratio, which was only noticed during these more systematic studies.

Latitudinal Distribution

A closer inspection of the historical data reveals another important feature of the global distribution. Data reported by Schmidt for 1971–72 indicated an H₂ level in surface air of the Northern Hemisphere that is about 6% higher than that observed in the Southern Hemisphere. The interhemispheric difference was only about 1.5% in the upper troposphere and a similar value (about 1.3%) was derived later by Schmidt from observations made in 1974.

In contrast, more recent observations show surface air mixing ratios that are consistently lower in the Northern Hemisphere than in the Southern Hemisphere. These observations are displayed in Figure 2. The most comprehensive global data set, that of Novelli and colleagues, obtained over the period from 1992 until 1995, indicates mean surface H₂ mixing ratios that are largest (about 540 ppbv) in the tropical region and decrease with increasing latitude to values close to 530 ppbv and 480 ppbv in the Southern and Northern Hemispheres, respectively. No new data for the free upper troposphere have become available in recent times.

Although there is no significant long-term trend in the historical record of the global mean mixing ratio (see Figure 1), the data plotted in Figure 2 suggest that the surface mixing ratios might have varied with time by some 3–4%. But the differences in the absolute H₂ levels of the three data sets, which amount to about 20–40 ppbv, might also be attributed to possible differences in the absolute calibration scales. However, there is clear evidence for a reversal of the relative, interhemispheric, difference of H₂ the mixing ratio over the last about three decades. This reversal is most probably due to a decrease of the mean H₂ mixing ratio in the Northern Hemisphere.

Seasonal Variability

The first systematic long-term measurements at monitoring stations revealed another cause of the observed natural

Figure 2 Observations of the latitudinal distribution of H₂ in the troposphere. Boxes represent average H₂ levels (and their 1 standard deviation uncertainty) in surface air and in the upper troposphere as observed by Schmidt (1974, 1978) between 1971 and 1974. Solid dots represent mean mixing ratios obtained by Khalil and Rasmussen (1990) from measurements at six sites over the period from 1985 to 1989. The heavy line shows the annual mean H₂ mixing ratios observed by Novelli *et al.* (1999) over the period 1992–95.

variability of H₂ in surface air: a pronounced seasonal variation. The amplitude of the seasonal cycle is about 20 ppbv in the Southern Hemisphere but is significantly larger, some 70 ppbv, in the Northern Hemisphere, in particular at higher northern latitudes. In fact, this seasonal variation is the cause of much of the observed asymmetry in hemispheric mean H₂ levels. The average latitudinal gradient displayed in Figure 2, derived from the comprehensive data collected at about 50 globally distributed sites, is due to the generally lower seasonal minima in the Northern Hemisphere.

In addition to this difference in amplitude, the seasonal cycles exhibit another interesting feature: a nonsymmetric timing of the seasonal minima and maxima. In the Northern Hemisphere, highest H₂ mixing ratios are observed in March and April (i.e., in early spring), while they are observed in the December to February period (i.e., in early summer) in the Southern Hemisphere; that is, the shift between both hemispheres is only 3 to 4 months. A typical example of the different timing of the seasonal cycles is shown in Figure 3, which compares the annual variation of H₂ at the stations Mace Head (53° N) and Cape Grim (42° S).

Figure 3 Seasonal variation of the H₂ mixing ratio in surface air at the monitoring sites Mace Head (53° N) and Cape Grim (42° S). Adapted from Simmonds *et al.* (2000).

H₂ Sources

The observed seasonal variation and its different timing in both hemispheres must be the consequences of a rather complex interaction of the production and destruction processes for atmospheric H₂. Moreover, the reversal of the interhemispheric H₂ distribution (see Figure 2) strongly suggests that the strength of some of the major source or sink processes must have changed over the last few decades. The global budget of H₂ is believed to be largely determined by natural processes. However, a number of important anthropogenic sources have also been identified. The sources are briefly discussed in the following sections. Updated estimates of the principal production rates were published by Ehhalt and by Novelli and colleagues.

Combustion Processes

Observations in urban air or continental air masses generally show higher mixing ratios than those in background tropospheric air. This suggests that industrial combustion processes and motor vehicle exhaust in particular are major sources of H₂. Direct quantification of the strength of this source is difficult. Best estimates rely on the correlation of the observed mixing ratio increments above the H₂ background values relative to that of carbon monoxide (CO), a trace gas for which the anthropogenic source is much better known. Novelli and colleagues, as well as Simmonds and colleagues, reported correlation ratios significantly lower than those reviewed by Warneck in 2000. Novelli and colleagues estimate the anthropogenic emission of H₂ from automotive exhaust and other technological processes as $15 \pm 10 \text{ Tg year}^{-1}$. Most of this production (between 80% and 95%) should be released in the Northern Hemisphere. Simmonds and colleagues reported substantially lower ratios of the H₂ and CO increments in European air masses. If these lower values are shown to be representative for the present global H₂ emissions from technological sources, the above estimate of this source must be

strongly reduced. Because anthropogenic emissions from fossil fuel combustion continue to increase steadily with time, absolute H₂ emission rates from fossil fuel use must have dropped substantially over recent decades in order to cause the observed reversal of the interhemispheric difference in the H₂ mixing ratio.

Biomass burning is another anthropogenic process that releases H₂ to the atmosphere. Estimates of this source are based mainly on measurements of the H₂/CO₂ concentration ratio measured in natural fire plumes and during laboratory combustion experiments. Novelli and colleagues reviewed previous estimates and reported a strength of this source as $16 \pm 5 \text{ Tg year}^{-1}$. It is generally believed that at least 80% of all fires are caused by humans. Most fires occur in the tropical region and in the extratropics of the Northern Hemisphere. Therefore, 60% of the total H₂ emissions from biomass burning are expected to occur in the Northern Hemisphere.

Photochemical Production

The photochemical oxidation of volatile hydrocarbons is by far the largest natural source of H₂. The reaction of methane (CH₄), the most abundant hydrocarbon in tropospheric air, with hydroxyl radicals (OH) initiates a reaction sequence ([I], [II], [III] and [IV]) that produces formaldehyde (HCHO).

Although the four reactions of this sequence do not fully describe the more complex chemical processes of CH₄ oxidation in the real natural troposphere, it may be assumed that each CH₄ molecule oxidized yields one HCHO molecule. The HCHO produced is either photolyzed in the sunlit atmosphere

via the two pathways ([V] and [VI]) or is destroyed by reaction with OH radicals as in reaction (reaction [VII]).

Only the second photolysis reaction (reaction ([VI])) leads to the formation of H₂. Therefore, the H₂ production rate depends on the relative rates of HCHO destruction via the three pathways, and will vary with altitude, daytime, and season. Assuming a mean global tropospheric OH concentration of about 10⁶ cm⁻³, as derived from global observations of methylchloroform (CH₃CCl₃), a global H₂ production through CH₄ oxidation of 26 ± 9 Tg year⁻¹ was estimated. Owing to the small interhemispheric gradient in the global distribution of CH₄, this H₂ source should be of the same magnitude in both hemispheres.

Similar reaction sequences produce HCHO during the oxidation of nonmethane hydrocarbons (NMHC); the oxidation of isoprene, for example, yields about 3 molecules of HCHO per isoprene molecule. However, the oxidation reaction sequences for the different compounds belonging to the group of NMHC species (e.g., isoprenes and terpenes) are much more complex than that for CH₄. Net HCHO yields depend on the amount of NO_x in the air mass and on the efficiency of heterogeneous reactions, in particular in the absence of sunlight. Furthermore, the global distributions, emission rates, and degradation processes for many NMHC compounds are only poorly understood, although these species are ubiquitous in the global troposphere. Therefore, global estimates of the H₂ production from these compounds have considerable uncertainties. Novelli and colleagues in 1999 estimated the global H₂ source from the oxidation of NMHC compounds in the range 14 ± 7 Tg year⁻¹. This production rate is about 30% lower than the estimate by Ehhlalt. Owing to the global partitioning of the NMHC emissions, about 70% of this H₂ production is released into the Northern Hemisphere.

Ocean Surface Waters

As a result of H₂ production by microorganisms, the surface waters of the Atlantic ocean were observed to be generally supersaturated by a factor of 3.0 ± 1.2 relative to surface air. If this value is assumed to be representative for all oceans, the global oceanic emission is estimated as 3 ± 2 Tg year⁻¹. According to the land-sea partitioning, about 60% of the total oceanic emission are released into the Southern Hemisphere.

Nitrogen Fixation

Another rather small source was identified by Conrad and Seiler, who observed that H₂ is released from soils that are covered by leguminous plants. H₂ production was correlated with N₂ fixation by bacteria that live in symbiosis in the root nodules of these plants. By extrapolating the measured correlation ratio to global conditions, these authors estimated the

annual H₂ production from this process to be about 3 ± 2 Tg year⁻¹. Because this source is coupled to vegetation, the release rate should be largest in the Northern Hemisphere and also show an annual variation with a maximum during the main growth period.

H₂ Sinks

Because there is no unambiguous indication of any long-term trend of the global H₂ abundance, the total H₂ production must be balanced by H₂ consumption of the same global strength. To date, only two notable removal processes have been identified.

Photochemical Destruction

Like many other trace gases, H₂ reacts with OH radicals (reaction ([VIII]))

The global tropospheric distribution of H₂ is rather uniform and its seasonal variation is relatively small (less than ±5%). Since the rate coefficient of this reaction is well known from laboratory experiments and the mean global OH concentration can be reliably derived from global measurements of methylchloroform (CH₃CCl₃) the global H₂ removal rate can be estimated to a relatively good precision. For a mean OH concentration of about 10⁶ cm⁻³, the global strength of the photochemical sink has been estimated as 19 ± 5 Tg year⁻¹. This is only about 25% of the total H₂ production. Owing to the small interhemispheric gradient in the global distribution of H₂, the removal rate should be of the same magnitude in both hemispheres.

Soil Uptake

A large number of experimental studies have revealed that uptake by natural soils is most probably the largest loss process for atmospheric H₂. The deposition velocities for various types of soil determined by several authors have been reviewed; they cover a broad range from 0.01 to 0.1 cm s⁻¹ and, if they are extrapolated to global loss rates, estimates of this sink include a large uncertainty. Global uptake rates ranging from about 15 to 110 Tg year⁻¹ have been reported in the literature. The average global loss rate for soils reported by Novelli and colleagues, 56 ± 41 Tg year⁻¹, leads to an almost balanced budget of global H₂ sources and H₂ sinks. Measurements of the isotopic composition of tropospheric H₂ showed, that the global loss rate due to soil uptake should be limited to about 60 Tg year⁻¹. The content of the heavier stable isotope deuterium (D) in atmospheric H₂ is rather high and H₂ released from the known sources has a relatively low D content. Therefore, the enhanced D/H ratio in atmospheric H₂ must be due to isotope fractionation that occurs during its decomposition in the loss processes. Because a large isotopic enrichment factor was measured for the reaction of H₂ with OH but only very small isotope effects were observed during soil uptake, Ehhlalt and colleagues

concluded from available data of D/H ratio in atmospheric and source H₂ that the global strength of the two sinks should be comparable in magnitude. The photochemical removal by reaction with OH can be estimated to a reasonably good precision, and isotope data put a strong constraint on the magnitude of soil uptake. In fact, global removal by soil uptake may be overestimated by a factor of 3 if calculations are based only on H₂ deposition velocities published in the literature.

The Tropospheric H₂ Budget

A summary of the production and loss rates for atmospheric hydrogen is given in Table 1). Updated estimates derived by Ehhlalt and by Novelli and colleagues are listed for comparison. The total sources and sinks appear to be balanced within the given range of uncertainties, but for some of the individual terms the numbers given in both budgets differ substantially. In particular, the largest distinct term in the H₂ budget — the loss rate due to uptake by natural soils — is still only poorly defined.

The budget terms of the global hydrogen cycle are compiled in Table 2), again based on the work by Ehhlalt and of Novelli and colleagues. From their data set collected at 50 globally distributed sites, Novelli and colleagues derived a global mean tropospheric H₂ mixing ratio of 531 ± 6 ppbv. Owing to the deeper minima in the seasonal cycle observed in the Northern

Hemisphere, there is about 3% less H₂ in the Northern than in the Southern Hemisphere. Assuming no vertical H₂ gradient in the troposphere, the authors calculate the global tropospheric burden of H₂ to amount to 155 Tg. This is very close to the number of 150 Tg reported by Ehhlalt in 1999. Assuming a global turnover of the order of 70.0 ± 35 Tg H₂ year⁻¹, one obtains a residence time of molecular hydrogen between 1.5 and 4.3 years, with an average value of 2.3 years.

The relative strengths of the sources and sinks and their partitioning between the hemispheres provide some clues to the puzzling features of the global H₂ distribution. The major portion of the global fossil fuel emissions is released into the Northern Hemisphere. A significant decrease of the strength of this source could explain the reversal of the interhemispheric gradient of the mean H₂ mixing ratio suggested by the historical data.

The role of soil uptake as the dominant H₂ sink seems to be a plausible explanation for the deeper minima in the seasonal cycles observed in the Northern Hemisphere because about 70% of the global removal takes place on the continental land surface in this hemisphere.

No satisfactory explanation is yet available for the observation of the asymmetry in the timing of the seasonal cycles in both hemispheres. As noted by Simmonds and colleagues, the seasonal cycle in the Southern Hemisphere with a maximum during local summer 'more closely reflects the photochemical nature of the main hydrogen source term than measurements in Northern Hemisphere midlatitudes'.

Novelli and colleagues argue that the maximum in the Southern Hemisphere might additionally be driven by biomass burning in the tropics. These authors also examined the effect of the hemispheric partitioning of the major source and sink terms of the H₂ budget (see Table 1). Their results suggest that the H₂ maximum observed in the Northern Hemisphere during late winter and early spring is 'largely driven by the absence of a strong sink combined with seasonally independent technological emissions and a maximum in tropical biomass burning'. They also argue that the H₂ minimum observed in the Northern Hemisphere during fall results from the combined effects of still relatively high photochemical H₂ removal and strong soil uptake.

Although some progress has been made in the qualitative explanation of the main features of the spatial and temporal distribution of tropospheric H₂, considerable uncertainties remain in most of the terms of the global budget. Further investigations of the budget of the H₂ isotopomer HD and of the fractionation of D to H during the major production and loss processes could help to reduce the present uncertainties. More observations of the ratio of H₂ and CO increments in tropospheric background air will help to decide on the importance of decreasing H₂ emissions from fossil fuel combustion as a cause for the reversal of the interhemispheric gradient of the H₂ mixing ratio.

Table 1 Estimates of sources and sinks of tropospheric H₂

Type	Novelli et al. (1999)	Ehhlalt (1999)
Sources (Tg year ⁻¹)		
Fossil fuel use emissions	15 ± 10	20 ± 10
Biomass burning	16 ± 5	10 ± 5
Oceanic emissions	3 ± 2	3 ± 2
CH ₄ oxidation	26 ± 9	15 ± 5
NMHC oxidation	14 ± 7	20 ± 10
N ₂ fixation	3 ± 1	3 ± 2
<i>Total sources</i>	77 ± 16	71 ± 20
Sinks (Tg year ⁻¹)		
Oxidation by OH	19 ± 5	25 ± 5
Soil consumption	56 ± 41	40 ± 30
<i>Total sinks</i>	75 ± 41	65 ± 30

Introduction

The key roles played by hydroxyl radicals (OH) within tropospheric chemistry, including the major sources, sinks, and chemical processes involving OH, are discussed. The major daytime sources of OH include the photodissociation of ozone (O₃) and nitrous acid (HONO), the photo-oxidation of formaldehyde (CH₂O) and acetone (CH₃C(O)CH₃), together with the ozonolysis of alkenes. Nighttime processes leading to OH production also include the ozonolysis of alkenes and, more importantly, nitrate radical (NO₃)-facilitated decomposition of peroxyacyl nitrates (RC(O)O₂NO₂) and NO₃-initiated oxidation of alkenes. The major sink processes for OH are to initiate the oxidation of carbon monoxide (CO), methane (CH₄), and a wide range of reactive volatile organic compounds (VOCs), and to form nitric acid (HONO₂) via reaction with NO₂. In the presence of sufficient NO and NO₂ (collectively termed NO_x), these oxidation mechanisms are propagated by organic peroxy (RO₂), alkoxy (RO), and hydroperoxy (HO₂) radicals. They regenerate OH and proceed with the formation of oxidants such as O₃, carbonyls (e.g., CH₂O), peroxides (e.g., hydrogen peroxide, H₂O₂), and organic nitrates (e.g., peroxyacetyl nitrate, PAN, CH₃C(O)O₂NO₂). OH and HO₂ chemistry may also lead to O₃ depletion under conditions of low NO_x. Finally, a brief description of several spectroscopic techniques that have been developed for quantitative ambient measurements of OH, together with their recent applications and intercomparisons in ground-based and airborne field studies of the tropospheric chemistry of OH, is also given.

Daytime Sources of OH in the Troposphere

Photodissociation of O₃

The primary daytime source of OH radicals throughout much of the troposphere is the photodissociation of O₃ in its near-ultraviolet (UV) absorption band, followed by reaction of the O(¹D) photoproduct with water vapor (reactions [I] and [II]).

However, both the O₃ absorption cross sections and quantum yields of formation of O(¹D) atoms decrease with increasing wavelength. Consequently, the rate of O₃ photodissociation, $j(\text{O}(\text{}^1\text{D}))$, and therefore the rate of OH production, varies strongly with changes in atmospheric path length that not only accompany spatial variations in altitude and latitude but also temporal variations on diurnal and seasonal time-scales. Indeed, as illustrated in Figure 1, daytime measurements of $j(\text{O}(\text{}^1\text{D}))$ and OH often display a high degree of positive correlation, especially in clean air that is characteristic of

remote environments and has relatively simple photochemistry. The rate of production of OH via O₃ photodissociation is also influenced by quenching of O(¹D) to O(³P) atoms via collision with tropospheric N₂ and O₂ (reaction [III]).

The fractional conversion, f , of O(¹D) into OH is described approximately by eqn [1], where $P_{\text{H}_2\text{O}}$ is the partial pressure of water vapor and P is the total pressure.

$$f = P_{\text{H}_2\text{O}} / [P_{\text{H}_2\text{O}} + 0.13(P - P_{\text{H}_2\text{O}})] \quad [1]$$

Photodissociation of HONO and Photo-Oxidation of CH₂O

Clearly, the factor, f , must be taken into account when comparing the relative importance of OH produced directly upon UV photodissociation of other precursor molecules. For HONO, photodissociation occurs on a time scale of approximately 15 min (reaction [IV]).

During the darkness of night, HONO concentrations may build up via heterogeneous hydrolysis of NO and NO₂, and as a result of direct emissions from motor vehicles. At sunrise, the photodissociation of HONO provides an early morning pulse of OH at a time of day when $j(\text{O}(\text{}^1\text{D}))$ is very low due to the long atmospheric path lengths and the low intensity of near-UV solar radiation. HO₂ is an important reactive intermediate of the photo-oxidation of CH₂O, and OH may be formed indirectly via the rapid reaction of HO₂ with reactions [V], [VI], [VII], and [VIII].

Urban environments often have high local emissions of CH₂O, whereas O₃ concentrations are generally suppressed due to rapid reaction with elevated levels of the primary pollutant, NO. Consequently, urban summertime rates of OH production via reactions [V], [VI], [VII], and [VIII] may exceed those via O₃ photodissociation by a factor of 4 or so for typical photodissociation rates and precursor concentrations.

Photo-Oxidation of CH₃C(O)CH₃

By contrast, the photo-oxidation of acetone, CH₃C(O)CH₃, which produces CH₂O as an intermediate species, has been suggested recently to be a significant source of HO₂ and OH (collectively termed HO_x) in the upper troposphere and

Figure 1 Simultaneous observations of OH (blue circles) and $j(\text{O}^1\text{D})$ (black line) made during the PRIME'99 campaign at the Silwood Park Atmospheric Research Station, near Ascot, UK. Data kindly provided by Professor M.J. Pilling and Dr D.E. Heard, University of Leeds, UK.

lower stratosphere (reactions [IX], [X], [XI], [XII], [XIII], [XIV], and [XV]).

Inclusion of this process in numerical models of atmospheric chemistry reduces considerably the discrepancies between calculated and measured HO_x concentrations and O_3 production rates.

Ozonolysis of Alkenes

The ozonolysis of alkenes ($\text{R}_1\text{R}_2\text{C} = \text{CR}_3\text{R}_4$) represents another important process that produces OH, and may even dominate the photodissociation of O_3 , HONO, and CH_2O in polluted urban environments. The initial reactions of alkenes with O_3 are generally slow, but, as shown in Table 1 may proceed at rates that are comparable to corresponding reactions of alkenes with OH occurring during daytime and with NO_3 during nighttime. Although the details are not yet understood fully, kinetic and mechanistic laboratory studies indicate that the electrophilic addition of O_3 across the double bond leads to the initial formation of an energy-rich primary ozonide ($[\text{R}_1\text{R}_2\text{COOOCR}_3\text{R}_4]^\ddagger$), which decomposes rapidly to generate pairs of energy-rich, carbonyl-substituted Criegee biradicals ($[\text{R}_1\text{R}_2\text{COO}]^\ddagger$ and $[\text{R}_3\text{R}_4\text{COO}]^\ddagger$), and primary carbonyl compounds ($\text{R}_1\text{C}(\text{O})\text{R}_2$ and $\text{R}_3\text{C}(\text{O})\text{R}_4$), according to reactions (reactions [XVI], [XVIIa], and [XVIIb]).

The Criegee biradicals either collisionally stabilize, isomerize and/or decompose to form OH and other organic radicals, for example by reaction [XVIII] or reaction [XIX].

More recent laboratory studies have also shown that the fractional yields of OH produced upon ozonolysis of alkenes are significant under simulated tropospheric conditions, with approximate values ranging from 0.1 for ethene to 0.85 for α -pinene. The ozonolysis of alkenes therefore represents a potentially important daytime source of OH that may lead to the net production of O_3 under certain conditions.

Nighttime Sources of OH in the Troposphere

NO_3 -Facilitated Decomposition of $\text{RC}(\text{O})\text{O}_2\text{NO}_2$ and Oxidation of Biogenic VOCs

Clearly, OH may also be produced during nighttime upon ozonolysis of alkenes. However, of more significance at night are other non-photochemical thermal reactions that involve NO_3 . NO_3 has a lifetime with respect to photodissociation of approximately 5 s during the day, and its daytime oxidation chemistry is much less important than that of the more reactive OH. However, under conditions of low NO_x , nocturnal NO_3 chemistry may lead to OH production by facilitating the decomposition of peroxyacyl nitrates ($\text{RC}(\text{O})\text{O}_2\text{NO}_2$), as shown in reactions [XX] and [XXI].

NO_3 may also initiate the oxidation of VOCs such as alkane hydrocarbons (RH), although, as shown in Table 1, these are particularly slow reactions [XXII].

Table 1 Comparison of tropospheric lifetimes of a range of CO and VOCs at typical ambient rural concentrations with respect to reaction with 1.6×10^6 molecule cm^{-3} OH, 30 ppbv O_3 , and 10 pptv NO_3

VOC	OH	O_3	NO_3
Carbon monoxide	30 days

ppbv, parts per billion by volume; pptv, parts per trillion by volume. Adapted without permission from Jenkin, M.E., Clemitshaw, K.C., 2000. Ozone and other secondary photochemical pollutants: Chemical processes governing their formation in the planetary boundary layer. *Atmospheric Environment* 34 (16), 2499–2527.

Nevertheless, subsequent reactions ([XXIII], [XXIV], [XXIV], [XXV], and [XXVI]) lead to OH production.

For dimethyl sulfide (DMS), which is of marine phytoplankton origin, and biogenic alkenes such as isoprene and terpenes, which are emitted by certain plants and trees, the primary step is the rapid addition of NO_3 rather than H atom abstraction. The subsequent reaction mechanisms are quite

complex, but in general, NO_3 oxidation of lesser alkyl-substituted alkenes leads to higher yields of HO_x (and bifunctional organic nitrates) and *vice versa*. Indeed, simultaneous observations of DMS, isoprene, terpenes, NO_3 , HO_2 , and RO_2 in the marine boundary layer and forested regions have provided increasingly convincing evidence for nighttime oxidation chemistry involving these species and, by implication, the production of OH. Unfortunately, confirmatory nighttime measurements of OH are relatively scarce, but concentrations of the order of $2\text{--}3 \times 10^4$ molecule cm^{-3} have been recorded on occasion. These data are a factor of $10^2\text{--}10^4$ less than typical maximum daytime OH values, and thus represent a significant observational achievement. Clearly, measurements of OH, NO_3 , HO_2 , and RO_2 , together with supporting data on O_3 , NO_x , HONO, HONO₂, and speciated VOCs and organic nitrates, would provide much improved understanding of the role of OH in nighttime oxidation chemistry.

Sinks and Reservoirs of OH in the Troposphere

Oxidation of CO

Figure 2 illustrates schematically the production of OH via O_3 and HONO photodissociation, the ozonolysis of alkenes, and the photo-oxidation of CH_2O . The mechanism of the oxidation of carbon monoxide (CO) in the troposphere is also shown. It is initiated solely by reaction with OH, propagated by HO_2 , which reacts with NO to regenerate OH and produce NO_2 , and proceeds via the photodissociation of NO_2 with the formation of O_3 (reactions [XXVII], [VI], [VIII], [XXVIII], and [XXIX]).

Reaction [XXX] is the overall net reaction.

This represents a chemical process that rapidly interconverts HO_x within seconds, NO_x within a few minutes, and does so without consuming either HO_x or NO_x .

Oxidation of CH_4

Similarly, as shown also in Figure 2, in the presence of sufficient NO, methylperoxy radicals (CH_3O_2), methoxy radicals (CH_3O), and HO_2 serve to propagate the OH-initiated oxidation of CH_4 . Once again OH is regenerated, in this case by reactions [XXXI], [XIII], [XIV], and [VIII], and O_3 is formed via reactions [XXXVIII] and [XXIX].

Figure 2 Daytime tropospheric chemistry illustrating sources of OH via photodissociation of O_3 and HONO, ozonolysis of alkenes, and the photo-oxidation of CH_2O . Reaction with OH initiates the oxidation of CO and CH_4 . In the presence of sufficient NO, OH is regenerated via reaction of NO with HO_2 , and O_3 is formed in cyclic reaction mechanisms. Reactions that interrupt or terminate these cycles represent loss processes for OH and HO_2 and include the production of $HONO_2$, H_2O_2 , CH_3OOH , and CH_3ONO_2 .

CH_2O is also produced and acts on a time scale of 5 h as a temporary reservoir species or secondary photochemical source of HO_2 (and thus OH) via reactions [V], [VI], [VII], and [VIII]. By contrast, in more remote environments with insufficient NO for reaction [VIII] to dominate the fate of HO_2 , O_3 is removed via reaction reaction [XXXII] with HO_2 , which yields OH.

Competition between reactions [VIII] and [XXXII] determines whether net production or loss of O_3 occurs.

The mutual reaction of OH and HO_2 , which is not shown in Figure 2, represents an important sink or termination process, which leads to a net loss of HO_x (reaction [XXXIII]).

By contrast, self- and analogous cross-reactions of HO_2 and CH_3O_2 lead to the formation of the HO_x reservoir species, hydrogen peroxide (H_2O_2), and methyl hydroperoxide (CH_3O_2H), via reactions [XXXIV] and [XXXV].

Figure 3 illustrates the percent contribution of the OH loss due to reaction with CO, CH_4 , and a wide range of biogenic and anthropogenic nonmethane hydrocarbons (NMHCs) as a diurnal cycle averaged over a field measurement campaign in

a forested region in Europe. In this case, isoprene was the dominant species reacting with OH during the day, whereas limonene and α - and β -pinene became more important during nighttime. These observations are consistent with their respective temperature- and light-dependent vegetative emission rates and OH reactivities.

Oxidation of NO_2 and SO_2

Apart from a wide range of VOCs and CO, the oxidation of inorganic compounds such as NO_2 and SO_2 is also initiated by reaction with OH, as shown by reactions [XXXVI], [XXXVII], [XXXVIII], and [XXIX].

The production of nitric acid in reaction [XXXVI] is the dominant loss mechanism for HO_x and NO_x in polluted atmospheres. Dry deposition and heterogeneous hydrolysis of NO_x are other important removal pathways. For SO_2 , however, reactions [XXXVII], [XXXVIII], and [XXIX] not only convert OH to HO_2 , but also lead to the formation of sulfuric acid (H_2SO_4), which rapidly condenses onto aerosol surfaces due to its low vapor pressure, thereby acting as a potential nucleus for new particle formation. SO_2 possesses high aqueous solubility and

Figure 3 The percent contribution of OH loss due to reaction with CO, CH₄, and a wide range of biogenic and anthropogenic non-methane hydrocarbons (NMHCs) as a diurnal cycle averaged over a field measurement campaign in a forested region in Europe. is therefore also oxidized in cloud droplets and precipitation, particularly via reaction with H₂O₂. To illustrate the wide range of compounds that OH reacts with, Table 2 lists estimated global emission rates of several important trace gases and the proportion that is removed via their reaction with an OH concentration of 1×10^6 molecule cm⁻³.

Comparison between Measured and Calculated OH Concentrations

For remote, clean air environments, the high level of agreement typically observed between OH concentrations measured directly and those calculated from a hierarchy of numerical models of the chemical and physical sources and sinks of OH, indicate that these relatively simple systems are sufficiently well understood. However, perhaps it is not surprising that, in chemically more complex systems such as urban environments

with many large sources of stationary and mobile anthropogenic pollutants, and forested regions that are characterized by a variety of biogenic emissions, the level of agreement between observations and calculations is typically less good. As described above, OH plays a central role in the tropospheric chemistry of most gas-phase organic and inorganic pollutants. Quantitative measurements of OH are invaluable in the validation of the chemical mechanisms and kinetic parameters incorporated within the models. Indeed, correct predictions of previously unidentified sources and sinks of OH, and of erroneous rate coefficient measurements, have resulted from the application of numerical chemical models to the interpretation of observational data sets from several field studies.

Measurement Techniques for Field Studies of OH Radicals

High reactivity with a wide range of VOCs, rapid interconversion with HO₂, lifetimes of the order of 0.1–1 s and highly variable, diurnal, seasonal, and spatial concentrations between 10^4 and 10^8 molecule cm⁻³ mean that the quantitative detection of OH remains one of the most important yet difficult challenges in tropospheric chemistry. Nevertheless, several field-proven, spectroscopic measurement techniques have been developed over the last two decades. Each technique is described briefly below, together with recent applications and intercomparisons in ground-based and airborne field measurement studies of the tropospheric chemistry of OH.

DOAS, L-POAS, and MOAS

DOAS (Differential Optical Absorption Spectroscopy) and L-POAS (Long-Path Optical Absorption Spectroscopy) are

similar to each other but distinct from MOAS (Multipass Optical Absorption Spectroscopy). The former are usually employed to measure over integrated optical path lengths of several kilometers, whereas the latter utilizes an open, wall-less White cell with a base length of 6 m to yield data that are more comparable with local, *in situ* measurements. Concentrations of OH are derived by applying least-squares fits of OH reference spectra to the recorded differential optical density using singular value decomposition routines. A considerable advantage of these optical spectroscopic methods for ambient measurements of OH is that calibration is achieved using data for absorption cross-sections predetermined in the laboratory. Unlike other techniques, sophisticated *in situ* calibration systems are not required. Detection limits of the order of 2×10^5 molecule cm^{-3} are achievable for optical path lengths of 2–5 km, with measurement frequencies of approximately 1 to 5 min. There have been several recent reports of the application of DOAS/L-POAS and MOAS to measurements of OH in ground-based studies in remote, rural, and more polluted environments.

LIF and FAGE

LIF (Laser-Induced Fluorescence) and FAGE (Fluorescence Assay by Gas Expansion) are essentially identical techniques. Ambient air is expanded as a continuous, supersonic free jet through a nominal 1 mm nozzle into a low-pressure detection chamber maintained at approximately 1 mbar. A laser beam at 308 nm is used to promote ground state $X^2\Pi$ OH into the first electronically excited state, $A^2\Sigma$. At low pressure, the fluorescence lifetime of OH is increased and allows delayed-gated photon counting to capture the extremely weak OH LIF signal, while discriminating against the much more intense scattered light. Interferences arising from the photodissociation of O_3 to $\text{O}(^1\text{D})$ atoms followed by subsequent reaction of $\text{O}(^1\text{D})$ with H_2O to form OH radicals during the laser pulse is negligible using 308 nm excitation at low pressure. Note that HO_2 may also be measured by reaction with NO in the low-pressure gas expansion chamber to form OH, which are subsequently detected as described above. Calibration requires not only measurement of the response to independently quantifiable sources of OH and HO_2 coupled to the inlet system, but also determination of the efficiency of conversion of HO_2 to OH. In addition to their increasing utility in photochemical reactor chambers, there have been several recent reports of the application of LIF/FAGE to measurements of OH (and HO_2) in ground-based, shipboard, and airborne studies of tropospheric chemistry in a variety of remote, marine, rural, and urban environments.

CIMS and IMR-MS

The development of CIMS (Chemical Ionization Mass Spectrometry) for the detection of OH in the atmosphere began in the late 1980s and 1990s. IMR-MS (Ion Molecule Reaction-Mass Spectrometry) is identical. In each case, OH radicals are reacted with $^{34}\text{SO}_2$ in the presence of O_2 to produce $^{34}\text{SO}_3$, which reacts with water vapor to form $\text{H}_2^{34}\text{SO}_4$ according to reactions [XXXVII]–[XXXIX]. $\text{H}_2^{34}\text{SO}_4$ is then detected using quadrupole mass spectrometry as the highly

stable anion, $\text{H}^{34}\text{SO}_4^-$, following H-atom abstraction by NO_3^- ions (reaction [XL]).

OH concentrations of less than 1×10^5 molecule cm^{-3} can be measured in less than 1 min. These techniques have also found increasingly widespread application in recent ground-based and airborne studies of the sources and sinks of OH in the troposphere.

Other Methods

Field measurements of ambient OH concentrations may also be made using a simple, portable and inexpensive method. This method utilizes the rapid reaction of OH with *o*-hydroxybenzoic acid in a buffered solution to produce 2,5-dihydroxybenzoic acid, which is quantified by reverse-phase high pressure liquid chromatography with fluorescence detection. In clean air, a detection limit of $3\text{--}6 \times 10^5$ molecule cm^{-3} may be achieved for a sampling period of 45–90 min. Tropospheric OH concentrations may also be determined from measurements of the differential loss rates of many NMHCs, especially reactive alkenes, in well-defined, summertime urban plumes. A key assumption is that the observed hydrocarbon losses are due solely to OH radical reaction, and that plume dilution is correctly accounted for. Finally, globally averaged OH concentrations of approximately 1×10^6 molecule cm^{-3} may be estimated from measurements of the global budget of methyl chloroform (CH_3CCl_3), which is entirely of anthropogenic origin and almost exclusively removed by reaction with OH. Clearly, information about regional- and local-scale sources and sinks of OH is not provided from such estimates, but the important role of OH in tropospheric chemistry on a global scale may be deduced.

Intercomparisons of Ambient Measurements of OH

Participation in intercomparison exercises represents an often undervalued but vitally important stage in the development and validation of new instrumentation and measurement techniques. Despite the undoubted importance of making ambient measurements of OH in order to understand further its central role in tropospheric chemistry, there have been relatively few intercomparison exercises carried out over the last two decades in order to compare measurement techniques. This may have been due partly to the difficult challenges posed, but this situation may change over the next decade with further evaluation of the more recently developed techniques in order to quantify their selectivity, accuracy, precision, detection limits, sensitivity, and reliability. However, those OH intercomparison exercises that have been carried out have been informative and instructive.

For example, an intercomparison of airborne measurements of OH was recently carried out above the Pacific Ocean. LIF and CIMS data recorded on DC-8 and P3-B aircraft, respectively, during two brief close proximity flights in the marine boundary layer showed exceptionally good agreement. Flights at an altitude of 5.5 km resulted in an average concentration difference similar to the measurement uncertainties of each technique of 40%, but much less than the

Figure 4 Bivariate plot of 137 OH data pairs measured by DOAS and LIF during the 1994 POPCORN campaign in a rural environment in north-east Germany. The correlation coefficient, r , is 0.90; the solid line represents a weighted linear fit with a gradient of 1.09 ± 0.04 and an intercept of $(0.28 \pm 0.15) \times 10^6 \text{ molecule cm}^{-3}$. Reproduced without permission from Hofzumahaus, A., Aschmutat, U., Brandenburger, U., et al., 1998. Intercomparison of tropospheric OH measurements by different laser techniques during the POPCORN campaign 1994. *Journal of Atmospheric Chemistry* 31 (1–2), 227–246.

combined uncertainties from all the contributing measurements. In each case, comparisons were made by normalizing the data with a photo-stationary state model. In addition, OH concentrations measured between 25° N to 25° S latitude over the entire longitude and altitude range of the study agreed to within 10%, although the ratio of DC-8:P-3B measurements increased at higher altitudes. These results illustrated no obvious measurement discrepancies and minimal common interferences and calibration errors for two quite distinct OH measurement techniques.

An intercomparison of extensive LIF and DOAS measurements of OH radicals in a rural environment in north-east Germany during August 1994 showed excellent agreement for the same air mass, thereby demonstrating impressively high degrees of specificity, accuracy and reliability. As shown in **Figure 4**, a linear relationship with a correlation coefficient, r , of 0.90, a gradient of 1.09 ± 0.04 and an intercept of

$0.28 \pm 0.15 \times 10^6 \text{ molecule cm}^{-3}$ was obtained from 137 data pairs. Earlier intercomparisons of ambient OH measurements using L-POAS and CIMS were carried out at Fritz Peak Observatory, Colorado, in 1991, and during the Tropospheric OH Photochemistry Experiment at Idaho Hill, Colorado, in 1993. In general, good agreement within 30% was obtained for similar chemical and meteorological conditions, which confirmed the absence of significant interferences or artefacts. A 1992 intercomparison of FAGE and an obsolete ^{14}CO radiocarbon technique not only demonstrated good correlation between data sets, with an r value of 0.86, but also revealed a significant unresolved calibration discrepancy of a factor of 2.9. Sadly, the first OH measurement intercomparison exercise in 1983–84 demonstrated the then unreliable airborne operation and insufficient detection sensitivities of LIF and the radiocarbon technique.

Introduction

The main environmental concern associated with mercury is accumulation of methylmercury in fish, which may, if the fish is consumed, cause significant adverse effects on humans. The fetus is especially sensitive, and consumption by the mother of contaminated fish during pregnancy can lead to irreversible damage to the central nervous system of the unborn child. The biogeochemistry of mercury is complex and involves accumulation in soils and sediments, methylation processes, and finally uptake and accumulation in aquatic food chains.

Although mercury in the atmosphere is normally present at mixing ratios below parts per 10^{12} (ppt), i.e. far below any levels at which risks to human health may occur, much attention has been given to understanding the atmospheric emissions, transport, transformations, and deposition of mercury.

Mercury differs from all other metals because it is the only one that exists in liquid form at room temperature. Mercury also has a relatively high vapor pressure. In the atmosphere, the predominant form of mercury is elemental monoatomic vapor.

This species is relatively stable and has an atmospheric lifetime in the range 0.5–2 years.

Mercury is present at background atmospheric concentrations around $1\text{--}2\text{ ng m}^{-3}$. Slightly lower values are found in the Southern Hemisphere, where anthropogenic emissions are lower than in the North. During the last 10–20 years, environmental concern over mercury pollution has led to increased research efforts to describe the atmospheric pathways of mercury from emissions to deposition. **Figure 1** shows a schematic description of the main atmospheric processes involving mercury.

Emissions

Mercury is emitted from a variety of anthropogenic and natural sources. Main anthropogenic sources include coal combustion, the cement industry, chlorine manufacturing plants, and waste incineration. Source strengths will vary within each category depending on the mercury content in the raw material and the extent to which control techniques have been employed. Natural sources include volcanoes and diffuse emissions from mercury-containing mineralizations.

Figure 1 Schematic representation of the main atmospheric processes involving mercury.

Different emission sources emit different fractions of mercury species (see Speciation below). The global anthropogenic emissions of mercury have been estimated to be 1900 t, with Asia contributing more than 50% and Europe and North America less than 25% each.

Natural emissions and reemissions are exceedingly difficult to quantify. Emissions from natural surfaces (soils and water) may also originate from previously deposited anthropogenic mercury as well as from natural sources. The variability in time and with geographical location is also considerable. Most estimates suggest that the natural emissions are of the same order of magnitude as the anthropogenic emissions.

Speciation

A key parameter for the understanding of the atmospheric cycling of mercury is the speciation. The main form of atmospheric mercury is elemental vapor (Hg^0), making up at least 95% of the total concentration as interpreted from ground-based measurements. The remaining fraction consists of trace levels of gaseous divalent mercury compounds such as the chloride (HgCl_2) and mercury associated with particulate matter (Hg(p)). While Hg^0 is relatively stable and can be transported over hemispheric or even global scales, HgCl_2 and Hg(p) are more readily deposited and can be regarded as local or regional pollutants (i.e. deposited within 10–1000 km). Organomercury species such as monomethylmercury (CH_3HgX , XCl, OH) are present in the atmosphere at a few picograms per cubic meter. The detection of permethylated (CH_3)₂Hg in ambient air is normally restricted to biologically active marine regions of upwelling deep water.

Since the low concentrations of atmospheric mercury species frequently preclude chemical or physical identification, operational measurement techniques are often used. Measurement data are typically presented as total gaseous mercury (TGM), reactive gaseous mercury (RGM), or total

particulate mercury (TPM). These species are defined on the basis of the specific sampling or analytical procedures as follows.

- Total gaseous mercury (TGM) comprises all gaseous mercury species collected by, for example, a gold amalgam sampling device. It consists mainly of Hg^0 and traces of divalent gaseous species such as HgCl_2 .
- Reactive gaseous mercury (RGM) comprises gaseous mercury species collected by a specific sampling device such as KCl-coated denuder or mist chamber. It consists of water-soluble gaseous divalent species such as HgCl_2 .
- Total particulate mercury (TPM) comprises mercury collected by a filter device, usually quartz fiber or fluorocarbon.

The most common analytical methods are cold vapor atomic fluorescence spectrometers (CVAFS) and cold vapor atomic absorption spectrometers (CVAAS). In both cases, mercury in a sample is transformed into Hg^0 vapor and released (either thermally or by purging with an inert gas) into a measurement cell. CVAFS is a significantly more sensitive technique than CVAAS but it requires detection in argon or helium, whereas CVAAS detection can be made in air.

Transformations

A number of transformation processes of atmospheric mercury have been identified experimentally over the last 10 years. These experimental studies have demonstrated the ability of closed-shell molecules (e.g., O_3 , Cl_2) and radicals (e.g., OH, Cl, Br) to oxidize elemental mercury in the gaseous and aqueous phases. A general conclusion is that the gas-phase reactions are generally slow, while those occurring in the aqueous phase may approach the diffusion-controlled limit. Despite this, the overall atmospheric oxidation rate is relatively slow because of the low solubility of Hg^0 in water. Moreover, a reversible redox balance is present in the

Table 1 Chemical reactions and rate constants. The use of bold type indicates the reactions most relevant to the atmospheric cycling of mercury

Reaction	Rate constant ($\text{l mol}^{-1} \text{s}^{-1}$ at ambient temperature if not stated otherwise)	Medium: gaseous (g) or aqueous (aq)
$\text{Hg}^0 + \text{O}_3 \rightarrow \text{HgO} + \text{O}_2$	18 ± 12	g
$\text{Hg}^0 + \text{OH} + \text{M} \rightarrow \text{HgOH} + \text{M}$	$(5.2 \pm 2.7) \times 10^7$	g
$\text{Hg}^0 + \text{Cl} + \text{M} \rightarrow \text{HgCl} + \text{M}$	9.0×10^9 at 120–170°C	g
$\text{Hg}^0 + \text{Br} + \text{M} \rightarrow \text{HgBr} + \text{M}$	1.6×10^8 at 120–170°C	g
$\text{Hg}^0 + \text{BrO} \rightarrow \text{products}$	$\geq 2.7 \times 10^7$	g
$\text{Hg}^0 + \text{H}_2\text{O}_2 \rightarrow \text{products}$	≤ 480	g
$\text{Hg}^0 + \text{Cl}_2 \rightarrow \text{products}$	$\leq 24\,000$	g
$\text{Hg}^0 + \text{NO}_3 \rightarrow \text{HgO} + \text{NO}_2$	$\leq 2.4 \times 10^6$	g
$(\text{CH}_3)_2\text{Hg} + \text{OH} \rightarrow \text{CH}_3\text{HgOH} + \text{CH}_3$	$(1.2 \pm 0.1) \times 10^{10}$	g
$(\text{CH}_3)_2\text{Hg} + \text{Cl} \rightarrow \text{CH}_3\text{HgCl} + \text{CH}_3$	$(1.7 \pm 0.2) \times 10^{11}$	g
$(\text{CH}_3)_2\text{Hg} + \text{NO}_3 \rightarrow \text{HgO} + 2 \text{CH}_3 + \text{NO}_2$	$(4.5 \pm 1.6) \times 10^7$	g
$\text{Hg}^0 + \text{OH} \rightarrow \text{HgOH}$	$(2.4 \pm 0.4) \times 10^9$	aq
$\text{HgX} + \text{O}_2 \rightarrow \text{HgX}^+ + \text{O}_2^-$ (XOH, Cl etc.)	$\sim 10^9$	aq
$\text{HgSO}_3 + \text{H}_2\text{O} \rightarrow \text{Hg}^0 + \text{HSO}_4^- + \text{H}^+$	0.6 s^{-1}	aq
$\text{CH}_3\text{HgCl} + h\nu \rightarrow \text{CH}_3 + \text{HgCl}$	$\sim 1 \times 10^{-6} \text{ s}^{-1}$ in summer and at 60° N	aq
$\text{Hg}^0 + \text{O}_3 \rightarrow \text{HgO} + \text{O}_2$	$(4.7 \pm 2.2) \times 10^7$	aq
$\text{Hg}^0 + \text{HClO}/\text{ClO}^- \rightarrow \text{products}$	$\sim 2 \times 10^6$	aq

aqueous phase involving reduction of divalent mercury by S(IV) complexes and possibly HO₂ radicals, further lowering the overall oxidation rate. Monovalent mercury compounds are transient species formed in the reactions of mercury. Being a radical, monomeric monovalent mercury in the aqueous phase is very susceptible to oxidation by molecular oxygen. Hg(II) complexes that are formed undergo very rapid equilibration with the ligands present.

In polar atmospheres, Hg⁰ can exhibit a very different behavior. The specific photochemistry occurring during polar sunrise increases the oxidizing capacity to such an extent that the atmospheric boundary layer can be almost completely depleted of Hg⁰. The Hg⁰ depletion occurs simultaneously with that of surface ozone, which is strongly affected by autocatalytic release of bromine to the gas-phase. The strong temporal correlation between Hg⁰ and O₃ depletion suggest linked chemistry, possibly involving the same families of chemical species. Strongly oxidizing bromine monoxide is also abundant above the boundary layer, in the free troposphere, where it may influence the speciation of mercury.

The atmospheric fate of (CH₃)₂Hg is controlled by rapid chemical degradation to products that are mainly removed via dry and wet deposition. The major reaction products consist of CH₃HgX derivatives, while a complete cleavage of both Hg–C bonds appears to occur when the oxidizing agent can transfer oxygen atoms.

To evaluate the importance of different oxidizing reactions, the chemical lifetime of Hg⁰ ($= k^{-1}[\text{oxidant}]^{-1}$) can be calculated using the rate constants presented in Table 1 and the relevant concentration ranges in which the oxidants are present. The resulting lifetimes are presented in Figure 2.

Air–Surface Exchange

Interactions with water, vegetation, and soil surfaces are an important characteristic of the atmospheric cycling of mercury. Significant emissions (or reemissions of previously deposited mercury) occur from natural waters. In principle, oxidized mercury deposited via wet or dry processes can be reduced in surface waters and reemitted to the atmosphere. Mercury also interacts with vegetation via dry deposition and reemissions.

Figure 2 Residence time of Hg⁰ in the troposphere due to gasphase chemical degradation. The ranges of mixing ratios are taken from the literature. No temperature correction of the rate of reactions given in Table 1 has been made. (A) Light line corresponds to conditions during the Polar spring ozone depletions and hatched line to concentrations measured in the free troposphere. (B) Applies only to polar tropospheric ozone depletions. (C) Light line corresponds to conditions during the polar spring ozone depletions and hatched line to estimates of annual global mean concentrations. (D) Hatched line indicates annual global mean concentrations.

Wet Deposition

While dry deposition of gaseous divalent mercury and particulate phase mercury can contribute significantly to the overall deposition flux, the main removal process of atmospheric mercury is wet deposition. Gaseous divalent or particulate mercury is either incorporated directly into clouds or washed out by precipitation.

Occurrence

Mercury is a natural component of the atmosphere. Anthropogenic activities have increased the atmospheric concentrations and deposition fluxes by a factor of 2–5. Typical concentrations of atmospheric mercury species are presented in Table 2.

Table 2 Typical concentrations of mercury species in the planetary boundary layer

Species	Concentration range	Location
Hg ⁰	0.5–1.2 ng m ⁻³ 1.1–1.8 ng m ⁻³ 1.5–15 ng m ⁻³	Atlantic air, Southern Hemisphere Atlantic air, Continental background, Northern Hemisphere Continental air, urbanized, industrial
RGM	–30 pg m ⁻³ (very variable)	Background air, marine and continental, higher near sources
TPM	0.1–5 pg m ⁻³ 5 to > 50 pg m ⁻³	Background air Continental background, higher near sources.
CH ₃ HgX	0.1–5 pg m ⁻³	Background air
(CH ₃) ₂ Hg	<5 pg m ⁻³	Background air
Hg(II) in precipitation	–30 pg m ⁻³ (very variable and normally <5 pg m ⁻³) 1–20 ng l ⁻¹	Marine polar air

RGM, reactive gaseous mercury; TPM, total particulate mercury

This article is a revision of the previous edition article by D H Ehhalt, A Wahner, volume 6, pp 2415–2424, © 2003, Elsevier Ltd.

Synopsis

The oxidizing capacity of the troposphere relies on oxidants such as O₃, NO₃, and OH. Of these, OH is by far the most important. The supply of all the oxidants is limited and thus the oxidizing capacity is finite. The factors that control OH, O₃, and NO₃ are reviewed and examples of their tropospheric distributions are presented. The resulting lifetimes of the most important tropospheric trace gases are listed. The possible change of the oxidant distributions under the impact of anthropogenic emissions is indicated. A quantitative measure of the oxidation capacity is derived from the total loss rate of all trace gases due to OH.

Introduction

The term 'oxidizing capacity' is widely used, but loosely defined. Its attraction is that it conveys in a succinct manner, two major features of atmospheric chemistry: namely, that the atmosphere actively oxidizes gaseous trace constituents and pollutants, and thereby initiates their removal from the atmosphere; and also, that this capacity is finite. The first feature is not unexpected; after all molecular oxygen, O₂, is a major constituent of the Earth's atmosphere. The second is somewhat surprising – considering that O₂ is present at about 21%, whereas the most abundant oxidizable trace gases are present at ppm level. The explanation is, of course, that O₂ does not directly react with those molecules. Tropospheric oxidation is rather initiated by a number of oxidants, above all by the hydroxyl radical, OH, but also by ozone, O₃, the nitrate radical, NO₃, and to a lesser extent by chlorine (Cl) and bromine (Br) atoms. Ground state atomic oxygen, O(³P), plays only a very minor role. In the liquid phase, for example in cloud droplets, hydrogen peroxide also acts as an oxidant. All these molecules and radicals are generated within the troposphere, and the rates of the respective generation processes limit their supply and thus the oxidizing capacity of the troposphere.

In the following, we briefly review the factors that control the tropospheric concentrations of the major oxidants, OH, O₃, and NO₃. We present examples of their tropospheric distributions, and indicate how these may have changed under the impact of anthropogenic emissions. From the superposition of the various loss processes, we derive the atmospheric lifetimes for the most important tropospheric trace gases. Finally, based on all this information we present a measure of the tropospheric oxidizing capacity through an approximate but simple expression.

The Tropospheric Chemistries of OH and O₃

The tropospheric chemistries of OH and O₃ are very closely interlinked. In fact, the primary production of OH is based on the photolysis of O₃. At wavelength below 340 nm, this photolysis yields electronically excited oxygen atoms, O(¹D) (eqn [I]):

Most of the O(¹D) atoms produced in reaction [I] are quenched to ground state atomic oxygen, O(³P), in collisions with atmospheric nitrogen and oxygen molecules (eqns [II] and [III]), but a fraction collides with water vapor molecules, to form the very reactive hydroxyl radical, OH (eqn [IV]).

H₂O is ubiquitous in the troposphere. For instance, in surface air at midlatitudes, H₂O is present at a volume mixing ratio of about 1%. There about 10% of the O(¹D) generate OH, because reaction [IV] has a rate constant of approximately a factor of 10 higher than the quenching reactions [II] and [III].

The conversion of O₃ to OH via the reactions [I] and [IV] at the same time forms a major sink of tropospheric O₃, whereas the O(³P) formed by [II] and [III] returns to O₃ by recombination with O₂ (eqn [V]).

The same holds for the O(³P) formed directly in the photolysis of O₃ at wavelengths longer than 320 nm (eqn [VI]).

The generation of O(³P) mainly by photolysis (eqn [VI]) but also by reactions [II] and [III] and others is balanced by the loss due to recombination. During daytime this results in a steady-state concentration of a few thousand O(³P) per cm³. Given the relatively low reactivity of O(³P), this concentration is too small to be of significance for the oxidation of trace gases in the troposphere. The fact that the O atoms generated in reaction [VI] interact rapidly with one of the major constituents of air limits their possible importance.

Hydroxyl radicals, on the other hand, do not react with any of the major constituents of air. Rather, they have the ability to initiate chain reactions in an O₂-containing atmosphere. When reacting with trace gas molecules, OH is not consumed, but is regenerated in catalytic cycles. In this way, relatively large OH concentrations, up to 10⁷ cm⁻³, are maintained in the sunlit troposphere despite the high reactivity of OH toward most pollutants and other trace gases. These two properties, high

reactivity and relatively high concentrations, make OH the most important oxidizing agent in the troposphere.

OH Reaction with Molecules

The simplest example of such a reaction is given by the atmospheric oxidation of carbon monoxide. The reaction of CO with OH immediately forms the stable end product CO₂ (eqn [VII]).

The reaction also forms a hydrogen atom, which is very reactive. The hydrogen atom rapidly combines with O₂ to form a hydroperoxy radical, HO₂ (eqn [VIII]).

The addition of a hydrogen atom to O₂ weakens the bond between the oxygen atoms, and HO₂ reacts much more readily than O₂. In particular, HO₂ oxidizes nitric oxide, NO (eqn [IX]).

In the planetary boundary layer over the industrialized and highly populated continents, where daytime concentrations of NO exceed 0.1 ppb, reaction [IX] is by far the fastest HO₂ reaction. Most important for our present argument is the fact that the OH radical consumed in reaction [VII] is regenerated in reaction [IX]. This is generally true: virtually all reactions of OH with molecular species lead to chain reactions that recycle OH. Reaction [IX] also highlights one of the roles of the nitrogen oxides for the OH budget. In the form of NO they quickly return the less reactive HO₂ back to the highly reactive OH, thus increasing the OH concentration.

The nitrogen dioxide molecule, NO₂, generated in reaction [IX] photolyzes readily in the near-UV region and therefore contributes to tropospheric photochemistry (eqn [X]).

In the sunlit atmosphere, the lifetime of NO₂ against photolysis is a few minutes. The resulting O atom immediately combines with O₂ to form O₃ (reaction [V]). This NO-mediated process consisting of reactions [IX], [X], and [V], in which an O atom from a peroxy radical is passed along to O₃, is the major ozone formation mechanism in the troposphere. It illustrates the fact that in an NO-containing atmosphere, trace gas removal is invariably linked with the production of O₃ or other photo oxidants. Supplemented by reactions [X] and [V], the hydroxyl radical reactions [VII]–[IX] combine to the net reaction shown in eqn [XI].

It does not consume OH, HO₂, NO, and NO₂, hence the cycle consisting of the reactions [VII]–[X] and [V] can be completed repeatedly before that chain reaction is interrupted by termination reactions. By this and other chain reactions, OH and HO₂ are interconverted within a matter of seconds. Therefore, both are often lumped together as HO_x.

The oxidation of more complex molecules, such as hydrocarbons, leads to other peroxy radicals, RO₂, which also convert NO to NO₂ and augment the generation of O₃. In addition, intermediates such as formaldehyde (HCHO) are formed,

whose photolysis leads to formation of HO_x and thus introduces a degree of autocatalysis.

Parallel to reaction [IX], HO₂ reacts directly with O₃ to return OH (eqn [XII]).

Thus even without NO there is a certain measure of recycling. But in this case the net result of the reaction chain, [VII], [VIII], and [XII], is a destruction of O₃ (eqn [XIII]).

Together with reaction [XIV], reaction [XII] forms the second important loss mechanism of tropospheric O₃, again closely tied to the HO_x chemistry.

Destruction of HO_x

To produce a net loss of HO_x and terminate the reaction chains, HO_x radicals have to react with other radicals. Eqns [XV] and [XVI] are responsible for HO_x loss in clean air.

The addition of OH to NO₂, forming a nitric acid molecule, HNO₃ (eqn [XVII]), is the dominant HO_x loss reaction in the polluted atmosphere.

At the same time, reaction [XVII] provides the major loss mechanism for NO_x. It also illustrates the tendency of atmospheric oxidation to produce acidic end products, which are eventually removed from the atmosphere by rainout.

The OH Balance Equation

The various production and destruction reactions of OH can be combined in a local OH budget equation of the type shown as eqn [1], where P_{OH} and D_{OH} stand for the local production and destruction terms of OH.

$$\frac{d[\text{OH}]}{dt} = P_{\text{OH}} - D_{\text{OH}} \approx 0 \quad [1]$$

In the case of a very short-lived species like OH, contributions from transport, i.e., the flux divergence, are small compared to P_{OH} and D_{OH} , and can be neglected. The same holds for the temporal change, $d[\text{OH}]/dt$.

P_{OH} consists of two, systematically different, terms: the primary production of OH (P_{OH}) through the photolysis of precursors such as O₃ or H₂O₂ and the OH produced from recycling HO₂ (Π_{OH}).

By far the largest contribution to P_{OH} on a global scale comes from the photolysis of O₃, which can be derived from reactions [I]–[IV] to give eqn [2].

$$P_{\text{OH}} = \frac{2[\text{O}_3] \cdot [\text{H}_2\text{O}] \cdot J_1 \cdot k_4}{k_2[\text{N}_2] + k_3[\text{O}_2] + k_4[\text{H}_2\text{O}]} + \dots \quad [2]$$

J_1 is the photolysis frequency of reaction [I], and the k_i refers to the rate constants of reactions [III]–[IV]. Smaller contributions,

such as that from the photolysis of H_2O_2 , are indicated by the ellipsis '...'.

Π_{OH} is determined by reactions [IX] and [XII] as eqn [3].

$$\Pi_{\text{OH}} = [\text{HO}_2] \cdot (k_9[\text{NO}] + k_{12}[\text{O}_3]) \quad [3]$$

D_{OH} , the destruction of OH, is given by eqn [4].

$$\begin{aligned} D_{\text{OH}} &= [\text{OH}] \cdot (k_7[\text{CO}] + k_{14}[\text{O}_3] + \cdots \\ &\quad + k_{17}[\text{NO}_2] + k_{15}[\text{HO}_2] + \cdots) \\ &= [\text{OH}] \cdot \tau_{\text{OH}}^{-1} \end{aligned} \quad [4]$$

A complete chemical mechanism would contain contributions to the production and destruction of OH other than those listed above. Again, these are indicated by the dotted ellipsis '...'. These additional terms would, however, fall in the same categories distinguished here. The first line in eqn [4] contains the reactions of OH with molecules, i.e., those that eventually generate HO_2 ; the second line contains the reactions of OH with radicals that lead to a net HO_x loss. The whole term in parenthesis in eqn [4] represents the pseudo-first-order reaction frequency or inverse lifetime, τ_{OH}^{-1} , of an OH radical.

We now define the recycling ratio $\rho = \Pi_{\text{OH}}/P_{\text{OH}}$. This is the number of HO_2 radicals converted to OH divided by the number of OH generated directly. We note that the precursors for direct OH production, mainly O_3 but also H_2O_2 , are also produced by OH chemistry, although not necessarily at the same location, and, thus, contain an element of recycling. Because of their long lifetime their recycling is slow and incomplete and their local concentration is largely determined by transport. We further note that Π_{OH} also includes a slow component, namely HO_2 derived from aldehyde photolysis, besides the fast recycling of HO_2 generated immediately after the OH attack. Nonetheless, for most of the troposphere, ρ also reasonably approximates the chain length, that is, the number of times an OH is recycled via HO_2 before it is removed by a radical–radical reaction. Introducing τ_{OH} and ρ , eqn [1] takes the simple form of eqn [5a] or eqn [5b].

$$P_{\text{OH}}(1 + \rho) - \frac{[\text{OH}]}{\tau_{\text{OH}}} = 0 \quad [5a]$$

or

$$[\text{OH}] = P_{\text{OH}} \cdot \tau_{\text{OH}}(1 + \rho) \quad [5b]$$

Equation [5b] demonstrates nicely that the ability of OH for chain reaction and slow recycling enhances its concentration by a factor $(1 + \rho)$ over that of a nonchain-reacting radical, whose steady-state concentration would be given merely by the product of its production and lifetime, $P \cdot \tau$. Tropospheric values for ρ vary between 0.3 and 10 depending on NO_x in a manner similar to that of OH shown in Figure 1. We note that the factors ρ and τ_{OH} still depend on the HO_x concentration. Thus, eqn [5b] by itself is not sufficient for calculating the OH concentration. It helps, however, to categorize the action of the various reactions on OH. The nitrogen oxides, $\text{NO}_x = \text{NO} + \text{NO}_2$, for example, act on OH in two different ways. In the form of NO, they accelerate the recycling from HO_2 to OH (reaction [IX]; cf eqn [3]) and thus enhance the concentration of OH; in the form of NO_2 they enhance the net loss of OH via reaction [XVII], and thus decrease τ_{OH} and

Figure 1 Dependence of the OH concentration and net O_3 production on NO_x calculated with a steady-state model for remote, rural conditions. Adapted from Ehhalt, D.H., 1999b. Photooxidation of trace gases in the troposphere. *Physical Chemistry Chemical Physics* 1, 5401–5408.

therefore the concentration of OH (cf eqn [4]). The opposing actions of the two processes lead to a highly nonlinear dependence of the OH concentration on NO_x (see Figure 1). At low NO_x , where recycling dominates, the addition of NO_x leads to an increase in OH concentration and thus to an increase in photochemical activity; at high NO_x , reaction [XVII] eventually becomes the dominant loss path of OH and further addition of NO_x reduces the OH concentration. The position of the maximum with respect to NO_x depends to some extent on the local mix of reactive trace gases. Except in polluted areas, however, tropospheric chemistry operates in NO_x regimes defined by the left flank of the OH curve in Figure 1; that is, an increase in global NO_x concentrations will lead to an increase in global OH.

The dependence of OH on other parameters is more monotonic, though still not linear. For the NO_x regime of the global troposphere, an increase in CO or other oxidizable molecules will lead to a decrease in OH (cf reaction [VII]; eqn [4]). But a change in H_2O will lead to a change of equal sign in OH (cf eqn [2]). Solar radiation acts through several channels: through P_{OH} via the photolysis of O_3 , but also through ρ and τ_{OH} , because photolysis of NO_2 shifts the $[\text{NO}]/[\text{NO}_2]$ ratio. These factors all conspire to give a nearly linear relationship between tropospheric OH and solar UV radiation.

Figure 1 also shows the dependence on NO_x of the net formation rate of O_3 given by $d[\text{O}_3]/dt = P_{\text{O}_3} - D_{\text{O}_3}$, where the local O_3 production, P_{O_3} , is maintained by reaction cycles such as that consisting of [VII]–[X] and [V]. The O_3 destruction, D_{O_3} , is given by reactions such as [XIII], [XIV], or [I] combined with [IV].

In the clean environment considered in Figure 1, the net O_3 production rate is relatively small; even at the maximum it amounts to no more than 2.3 ppbv h^{-1} . The profile of the net O_3 formation rate is similar to that of the OH concentration, i.e., to the photochemical activity. At low NO_x concentrations, however, it begins to deviate significantly, because there the O_3 -destroying reactions, such as reaction [I] combined with reaction [IV], remain active, whereas the O_3 -producing reactions, such as the sequence [VII]–[X], decrease with decreasing NO_x . Eventually, below an NO_x concentration of about 0.07 ppb, photochemistry leads to a net destruction of O_3 .

Chemistry of NO₃

The nitrate radical, NO₃, is formed primarily by the relatively slow reaction [XVIII].

However, in daylight NO₃ is photolyzed within tens of seconds via reactions [XIXa] and [XIXb].

In addition, NO₃ reacts rapidly with NO (eqn [XX]) that is always present during daytime owing to photolysis of NO₂ (reaction [X]) such that during daytime NO₃ remains at very low concentrations.

During nighttime, however, NO₃ can build up to significant concentrations because the remaining loss reactions are much slower. These are (1) the heterogeneous uptake of NO₃ by moist aerosol surfaces, fog, or cloud droplets; and (2) the heterogeneous uptake of N₂O₅, which is formed from combination of NO₃ with NO₂ (eqn [XXI]).

This reaction is important especially at low temperatures since the thermal decomposition of N₂O₅ to NO₂ and NO₃ is strongly temperature dependent. N₂O₅ reacts with condensed water to form HNO₃. It thus reacts rapidly upon collision with the wet surfaces such as cloud droplets or aerosol particles at relative humidities above 60%. In nights with high relative humidities, this reaction path together with the direct uptake of NO₃ provides an efficient loss of NO_x.

Finally, NO₃ reacts with organic molecules in a manner similar to OH but for most molecules much more slowly than the corresponding reactions with OH. Nevertheless, in polluted regions it can provide a significant loss for organic molecules.

Global Distributions of OH, O₃, and NO₃

The tropospheric chemistry outlined above maintains global distributions of OH, O₃, and NO₃ that vary with latitude, longitude, daytime, and season. For reference, Figure 2 presents the mean zonal distributions of OH, O₃, and NO₃ for January

Figure 2 Mean zonal distributions of OH, O₃, and NO₃ for January and July based on 3D chemical transport models. OH distribution (top panels, contour lines $\times 10^5$ OH cm⁻³) adapted from Spivakovsky, C.M., Logan, J.A., Montzka, S.A., et al., 2000. O₃ distribution (middle panels, contour lines ppbv) adapted from Wang, Y., Jacob, D.J., Logan, J.A., 1998. Global simulation of tropospheric O₃-NO_x-hydrocarbon chemistry. *Journal of Geophysical Research* 103, 10757–10767. NO₃ distribution (bottom panels, contour lines pptv), private communication Hauglustaine, D., 2000.

and July. They are based on 3D chemical transport models, since measurements are too sparse to allow a representative and consistent reconstruction of the average concentration fields. Nevertheless, the concentration fields shown are expected to closely approach reality. For O_3 , the measured seasonal variations, as well as height profiles, show good agreement with those modeled for the same sites. For OH, the globally averaged concentration agrees well with the value of $1.0 \times 10^6 \text{ cm}^{-3}$ derived empirically from the budget of methyl chloroform, CH_3CCl_3 .

The main oxidant, OH, shows a strong latitudinal variation at all altitudes, with a broad maximum in the tropics centered at the latitude of maximum solar radiation. It also varies with altitude with a broad maximum around 4 km at all latitudes. In addition, OH, as well as the other oxidants, O_3 and NO_3 , exhibits higher concentrations in the Northern Hemisphere whose continents provide most of the global emissions, whether natural or artificial. For the same reason, the longitude by latitude presentation (Figure 3) also indicates higher concentrations of OH over the continents.

The chemistry outlined above also predicts that the increase of the anthropogenic emissions of NO_x , CO, and CH_4 that accompanied the industrialization and population growth of the last century must have caused significant changes in the concentrations of the tropospheric oxidants. There is indeed

experimental evidence mainly from historical records over Europe that the concentration of O_3 has increased by about a factor of two over that period. Figure 4 presents the model-calculated change in the zonally and annually averaged distribution of O_3 and OH from preindustrial to present time. For O_3 the models predict a general increase of about 60%, which is, however, lower in the Southern Hemisphere (+50% in the case presented) than in the Northern Hemisphere (+80%). The model-calculated globally averaged OH decreased by about 10%, a relatively small value. However, as Figure 4 indicates, the changes are quite unevenly distributed, with large zones of substantial positive change. The OH concentration over the continents increased strongly, whereas it decreased over the oceans, mapping the nonuniform distribution of NO_x , which is short lived and mostly emitted over the continents. In fact, the global distribution of OH, as well as its trend, strongly depends on the assumed spatial and temporal distribution of the NO_x emissions. The most recent analysis of the CH_3CCl_3 budget suggests a relatively constant mean global OH concentration over the past 20 years with a small interannual variability of $2.1 \pm 1.8\%$ per year, but no significant long-term trend.

The difference between the global change for OH and O_3 is not unexpected. For O_3 the increased emissions of CO and NO_x reinforce each other, as more CO leads to higher formation of

Figure 3 Global distribution of OH for January (top panel) and July (bottom panel) at 700 mb (contour lines $\times 10^5 \text{ OH cm}^{-3}$). HO₂, which in turn is efficiently converted to O₃ by the enhanced NO. For OH they counteract each other – increased NO_x induces a larger and increased CO a lower OH concentration. For NO₃ one would also expect a global increase in the concentration field since preindustrial times, since both the NO₂ and O₃ concentrations have increased globally. However, no hindcasts have been published for NO₃.

Obviously, as long as the emissions of NO_x, CO, and CH₄ continue to grow, further changes in the global distributions of OH, O₃, and NO₃ have to be expected. For example, for the future emission scenario A1F1 from IPCC 2001, which presents one of the worst cases and assumes global emissions of NO_x, CO, VOC, and CH₄ of 243, 193, 198, and 128%, respectively, of the values in the year 2000, model calculations predict a decrease in the mean global OH of –14% and an increase in O₃ of 47% by the year 2100.

The Global Loss Rate

The removal of a given trace gas from the troposphere is usually generated by several different processes. In addition to the tropospheric oxidation by OH, O₃, NO₃, and other radicals, direct photolysis, dry deposition at the Earth's surface, and export to the stratosphere may play a role. For a gas X_i, the global tropospheric loss rate, L_i, is given by the sum of all the individual loss rates integrated over the volume of the troposphere and averaged over a full year. Correspondingly, the global tropospheric lifetime of a trace gas, τ_i, is defined as its tropospheric burden, M_i, divided by its global tropospheric loss rate. The contribution of the major oxidants to the global loss rate of X_i is given by eqn [6], where the brackets denote the local concentrations in units of cm^{–3}, the k_i are the respective rate constants, which generally depend on temperature and thus also on location and season, ν stands for tropospheric volume, t for time, and a = 1 year.

$$L_i = \frac{1}{a} \int_{\nu, t} (k_{i,OH} \cdot [OH] + k_{i,O_3} [O_3] + k_{i,NO_3} \cdot [NO_3]) \cdot [X_i] d\nu \cdot dt$$

$$= M_i \tau_i^{-1} \quad [6]$$

Examples of the rate constants are given in Table 1 for a few selected organic trace molecules. Clearly, the rate constants vary over many orders of magnitude, reactions with OH having the highest and those with O₃ the lowest rate constants. We also note that the ratios k_{OH}:k_{O₃}:k_{NO₃} vary substantially between the various trace gases. Thus the relative contributions of the global OH, O₃, and NO₃ fields to the global oxidation rate vary greatly with the trace gas considered.

Generally, however, tropospheric oxidation is dominated by reaction with OH. This is emphasized by Table 2, which lists the trace gases with the highest turnover in the atmosphere. The most important three trace gases, namely CO, CH₄, and H₂, are not attacked by O₃ or NO₃. In fact, significant direct oxidation by O₃ is limited to the terpenes and NO_x; and that by NO₃ to the terpenes and dimethyl sulfide. In terms of global tropospheric removal, direct attack of O₃ and of NO₃ adds up to a loss rate of 3.75 Tmol per year, i.e., about 2% of the total loss rate of 180 Tmol per year given by the sum over the individual trace gas losses in Table 2 and the oxidation of their secondary products. This does not preclude that oxidation by NO₃ and O₃ becomes important on a local scale, or for certain molecules even on a global scale, but its impact on the total turnover of oxidizable molecules is small. Similarly, the tropospheric role of Cl and Br atoms appears small. Based on the global budgets of ethane and tetrachloroethene, the average Cl atom concentration in the Northern Hemisphere has been estimated to less than 1000 cm^{–3} and in the Southern Hemisphere less than 2000 cm^{–3}. This is three orders of magnitude smaller than the globally averaged OH concentrations. This difference is so large that it cannot be compensated by the generally higher rate constants of hydrocarbons with Cl atoms. Finally, the role of H₂O₂ is pretty much limited to the oxidation of SO₂ in the liquid phase (Table 2) and its overall impact is on the order of 1% of the total loss rate of 180 Tmol per year.

As a consequence, the tropospheric oxidizing capacity is generally viewed as synonymous with the OH chemistry in the troposphere. Moreover, at least implicitly, the mean global OH abundance has been, and occasionally still is, used as a quantitative measure for the oxidizing capacity. Note that according to this measure, the oxidizing capacity is predicted not to have changed much over the last 100 years. At first glance this choice appears plausible, because OH determines the loss rates of many

Table 1 Rate constants of reactions of various organic trace molecules with OH, O₃, and NO₃. The rate constants are given for 298 K in cm³ molecule^{–1} s^{–1}. The respective lifetimes are calculated on the basis of following concentrations: OH: 1 × 10⁶ cm^{–3}, O₃: 30 ppbv, NO₃: 1 pptv

Organic	Rate constants (at 298 K)			Lifetimes		
	k _{OH}	k _{O₃}	k _{NO₃}	τ _{OH}	τ _{O₃}	τ _{NO₃}
n-Butane	2.4 × 10 ^{–12}	<10 ^{–22}	4.6 × 10 ^{–17}	4.8 days	–	28 years
Ethene	8.6 × 10 ^{–12}	1.6 × 10 ^{–18}	2.1 × 10 ^{–16}	32 h	9.6 days	6 years
Propene	2.9 × 10 ^{–11}	1.0 × 10 ^{–17}	9.5 × 10 ^{–15}	9.6 h	37 h	49 days
Trans-2-butene	6.4 × 10 ^{–11}	1.9 × 10 ^{–16}	3.9 × 10 ^{–13}	4.3 h	1.9 h	28 h
Isoprene	1.0 × 10 ^{–10}	1.3 × 10 ^{–17}	7.0 × 10 ^{–13}	2.8 h	28 h	16 h
α-Pinene	5.3 × 10 ^{–11}	8.7 × 10 ^{–17}	6.2 × 10 ^{–12}	5.2 h	4.1 h	1.8 h
Formaldehyde	8.5 × 10 ^{–12}	–	5.6 × 10 ^{–16}	33 h	–	2.3 years
CH ₃ CHO	1.5 × 10 ^{–11}	–	2.7 × 10 ^{–15}	19 h	–	170 days

Due to a strong anticorrelation induced by the oceanic emission of (CH₃)₂S and continental emission of NO₂ removal by NO₃ is less than that calculated from the global means (footnote a), (footnote c) which would assign 85% of the (CH₃)₂S loss to NO₃.

Adapted and expanded from Ehhalt, D.H., 1999a. Chapter 2: Gas phase chemistry of the troposphere. In: Zellner, R. (Guest ed.), Baumgärtel, H., Grünbein, W., Hensel, F. (eds.), Global Aspects of Atmospheric Chemistry, Topics in Physical Chemistry, vol. 6. Steinkopff, Darmstadt, pp. 21–109.

trace gases (see Table 2), such that the knowledge of global OH allows a straightforward estimate of the mean global lifetimes of the individual trace gases. However, taken by itself, the OH concentration says nothing about the rates of the photochemical system and thus nothing about the absolute strength of the oxidizing capacity. A regional example illustrates the point: The OH concentrations in the lower and upper troposphere are about equal (Figure 2). Nevertheless, the loss rate of CH₄ in the upper troposphere is more than a factor of 10 lower than in the lower troposphere, because of the lower temperature and lower CH₄ concentration of the former. In addition, this measure provides little immediate insight into the parameters controlling the oxidizing capacity of the troposphere.

Therefore, more recently, another more appropriate measure for the oxidizing capacity has been introduced. This consists of the total annual oxidative loss of trace gases in the troposphere, L_t (eqn [7], with L_i defined by eqn [6]).

$$L_t = \sum_i L_i \quad [7]$$

Restricting, as above, the losses considered to those facilitated by OH, the integrand for $\sum_i L_i$ becomes identical to D_{OH} (eqn [4]), the local loss rate of OH, with one exception: the term $k_{15} [\text{HO}_2][\text{OH}]$ does not appear among the L_i . This term, however, contributes only about 1% to the sum defining D_{OH} , so that this difference can be safely neglected. Thus we obtain eqn [8], where L_{OH} is the annual mean global loss rate of OH.

$$L_t \equiv \frac{1}{a} \int_{v,t} D_{OH} dv dt = L_{OH} \quad [8]$$

Using eqn [5b], we can rewrite eqn [8] as eqn [9].

$$\begin{aligned} L_t \equiv L_{OH} &= \frac{1}{a} \int_{v,t} P_{OH}(1 + \rho) dv dt = (1 + \bar{\rho}) \frac{1}{a} \int P_{OH} dv dt \\ &= (1 + \bar{\rho}) P_{OH,g} \end{aligned} \quad [9]$$

The total oxidative loss rate of trace gases is given by the total loss rate of OH, which in turn is identical to the annual global primary production rate of OH, $P_{OH,g}$, multiplied by an appropriately averaged feedback factor $(1 + \bar{\rho})$. In other words, this measure for the oxidizing capacity is identical to the total global supply of OH. This definition has several advantages:

1. It quantifies the total trace gas loss initiated by OH in the troposphere.
2. It indicates directly the essential dependences of the oxidizing capacity on its controlling parameters. Since P_{OH} is essentially given by the photolysis of O₃, i.e., $P_{OH} \sim J_1[\text{H}_2\text{O}][\text{O}_3]$ (see eqn [2]), it is clear that $P_{OH,g}$ is dominated by the tropospheric fields of O₃, H₂O, and solar UV radiation. All of these are influenced to some extent by human activities – for example, O₃ by tropospheric chemistry acting on anthropogenic emissions, H₂O by a warming climate, and solar UV by the loss of stratospheric O₃. Clearly ρ is also influenced via tropospheric chemistry, but see point (4) below.
3. This measure also suggests that the oxidizing capacity of the troposphere depends via O₃ and ρ on the emissions of NO_x and volatile organic compounds and thus may respond with some resilience to the load placed on it by anthropogenic emissions, for example, by increasing the burden of tropospheric O₃.
4. It directly indicates that the oxidizing capacity will always remain finite, since both, $P_{OH,g}$ and $\bar{\rho}$ remain finite for any foreseeable emission scenario. For the present troposphere, $P_{OH,g}$ and $\bar{\rho}$ can be estimated from 3D model calculations to about 108 Tmol per year and 0.74, respectively; the corresponding values for the preindustrial troposphere were 71.5 Tmol per year and 0.62. For very high loads of certain pollutants, $\bar{\rho}$ can become negligibly small. Thus, if the global emission flux of NO_x was to exceed $P_{OH,g}$, the global OH abundance would be successively titrated away by reaction [XVII], while the NO_x burden would build up until checked by other losses. It has been pointed out that such

events of overwhelmed oxidation capacity can be observed regionally over areas with high NO_x emissions. There, during wintertime when the flux of solar UV is low, the levels of oxidants such as O_3 and H_2O_2 are greatly reduced in favor of a buildup of the primary pollutants, NO_x and hydrocarbons, quite in contrast to summertime conditions. In such a case, the oxidizing capacity is limited to $P_{\text{OH},g}$. Generally, however, emissions of NO_x and oxidizable molecules have increased together causing an increase in $\bar{p}$.

The new measure, L_v , predicts a substantial increase of the tropospheric oxidizing capacity, about 60%, over the past 100 years, mainly because of the increase of global O_3 by about 60%, but also due to an increasing $\bar{p}$ as a consequence of the global increase in NO_x . The same conclusion can be reached directly from eqn [8], since the predicted global abundance of OH decreased by only 10%, whereas the predicted concentrations of the major molecules CH_4 and CO increased by a factor of 2–3, greatly enhancing the total global loss rate of trace gases.

The model-derived value of L_t for the oxidizing capacity of the present troposphere is 188 Tmol per year. This value includes the oxidation of secondary products such as HCHO. It is uncertain, because the actual emissions of the various tropospheric trace gases are uncertain and some of the minor trace gases may not be treated in the models at all. Moreover, the degradation pathways of some hydrocarbons are still not fully understood and may include OH recycling processes, not considered so far. Such seems to be the case for isoprene. Thus, the above value for L_t may rather represent a lower limit for the current oxidizing capacity of the troposphere.

Synopsis

Peroxyacetyl nitrate (PAN; $\text{CH}_3\text{C}(\text{O})\text{OONO}_2$) is an important constituent of photochemical smog. It is also a ubiquitous chemical present throughout the global troposphere. A unique property of PAN is that it is very stable at cold temperatures and easily decomposes to release NO_x at warm temperatures. In remote atmospheres, it can act as a carrier and a reservoir of NO_x , which is necessary for ozone (O_3) formation. Peroxyacetyl nitrates (PANs) are known to be eye irritants (lachrymators), phytotoxins, and bacterial mutagens. The most serious biological effects of PANs are of a phytotoxic nature resulting in injury to plants and vegetation.

Introduction

Peroxyacetyl nitrate (PAN; $\text{CH}_3\text{C}(\text{O})\text{OONO}_2$), also known as peroxyacetic nitric anhydride, was first identified as a component of Los Angeles smog in the 1950s. Among the large number of peroxyacetyl nitrates (PANs; $\text{RC}(\text{O})\text{OONO}_2$) that have been found to be present in the ambient air, PAN is the most abundant. Other commonly observed but much less abundant chemicals in this series are peroxypropionyl nitrate (PPN; $\text{C}_2\text{H}_5\text{C}(\text{O})\text{OONO}_2$), peroxybenzoyl nitrate (PBzN; $\text{C}_6\text{H}_5\text{C}(\text{O})\text{OONO}_2$), peroxyacryloyl nitrate (APAN; $\text{CH}_2=\text{CHC}(\text{O})\text{OONO}_2$), peroxyisobutyryl nitrate (PiBN; $(\text{CH}_3)_2\text{CHC}(\text{O})\text{OONO}_2$), and peroxymethacryloyl nitrate (MPAN; $\text{CH}_2=\text{C}(\text{CH}_3)\text{C}(\text{O})\text{OONO}_2$). A unique property of PANs is that they are not directly emitted from any known source. They are all products of atmospheric photochemical reactions involving hydrocarbons and nitrogen oxides (NO_x). This makes them excellent indicators of photochemical activity. PANs are chemical pollutants that can cause damage to agricultural crops and are often the reason for eye irritation felt by many people on smoggy days. In recent decades, it has been shown that PAN is not merely a pollutant but is a ubiquitous chemical present throughout the global troposphere. In remote atmospheres, it can act as a carrier and a reservoir of NO_x , which is necessary for ozone (O_3) formation. Here, we discuss mechanisms for the atmospheric formation and destruction of PAN, its measurement methods, concentrations in polluted and remote air, role in atmospheric chemistry, and potential biological effects.

Physical and Chemical Properties

At standard temperature and pressure, PAN exists as a colorless liquid with a melting point of -48.5°C and a boiling point of 104.5°C . Its vapor pressure closely follows the equation $\ln P (\text{hPa}) = -4586/T(\text{K}) + 19.04$. It is nearly insoluble in water (Henry's coefficient is 3.5 M atm^{-1} at 22°C ; $\text{M} = \text{mol l}^{-1}$) but is highly soluble in nonpolar organic solvents and hydrolyzes rapidly in basic solution. It is explosive in pure form and finds no commercial application. In the atmosphere, it is formed from the reaction of peroxyacetyl (PA; $\text{CH}_3\text{C}(\text{O})\text{OO}$) radicals with NO_2 . Although PA radicals can be formed in

many ways, their most common precursors are carbonyls (such as acetaldehyde, acetone, and biacetyl). These carbonyls are often secondary products of atmospheric reactions involving hydrocarbons and oxidants such as O_3 and hydroxyl (OH) radicals. They can also be directly emitted from natural and artificial sources. Hydrocarbons in general are oxidized by reaction with OH radicals and the resulting peroxy (RO_2) radicals react with NO to produce a variety of carbonyls as a product. Below is an example of the formation of acetaldehyde (CH_3CHO) and acetone (CH_3COCH_3) from the oxidation of ethane and propane, respectively.

It should be noted that each of the above reactions involves multiple steps. The carbonyls thus formed are highly reactive and break down to produce PA radicals, which can react with ambient NO_2 to form PAN. While PAN formation primarily requires sunlight, its synthesis is also possible at night. Not all PA radicals produce PAN, however, some also react with NO and HO_2 in ways that ultimately produce formaldehyde and peracetic acid, respectively. Molecules such as acetone are uniquely effective in forming PA radicals (and PAN) directly in the upper troposphere.

Atmospheric abundance of PAN is strongly affected by its loss processes. The most important of these is thermal dissociation (TD). This loss rate is an extremely strong function of temperature and hence varies greatly in the atmosphere. The

various rate constants that apply to the equilibrium of PAN with NO_2 are listed below. At warm temperatures, as may be encountered in the boundary layer, PAN dissociates rapidly (hours) and the equilibrium is shifted toward NO_2 . At colder temperatures, as may be encountered in the upper troposphere, PAN is very stable and this reaction is shifted greatly in favor of PAN.

$$k_1 = k_0[\text{M}]\{1 + k_0[\text{M}]/k_\infty\}^{-1}0.3\{1 + (\log k_0[\text{M}]/k_\infty)^2\}^{-1}$$

$$k_0 = 4.9 \times 10^{-3} \exp(-12\,000/T) \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1};$$

$$k_\infty = 4.0 \times 10^{16} \exp(-13\,600/T) \text{ s}^{-1}; k_1/k_{-1} = 1.11 \times 10^{28} \exp(-14\,000/T) \text{ molecule cm}^{-3}.$$

PAN absorbs UV radiation in the troposphere and its absorption cross sections have been measured from 195 to 345 nm wavelengths at several representative temperatures. The absorption is considerably slower at colder temperatures. Breakdown via photolysis removes PAN with an e-fold ($1/e$) time (lifetime) of approximately 3 months. PAN also reacts with OH radicals, but this rate has been found to be extremely slow ($k \leq 3 \times 10^{-14} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$) and provides an ineffective removal process. Figure 1 shows the loss rates of PAN in the troposphere calculated for these processes for July 1 and 30° N conditions and a standard atmosphere. It is clear that thermal loss completely dominates in the lower troposphere. Above 7 km, PAN loss is slow and is dominated by photolysis. PAN has extremely low solubility in water ($H = 3.5 \text{ M atm}^{-1}$ at 22° C) and removal by washout or rainout processes is unimportant. Near the surface of the earth, PAN is also lost by dry deposition. Typical deposition velocities over soil/grass and oceans/water surfaces of 0.25 and 0.01 cm s^{-1} , respectively, have been measured. PPN removal rates from all these processes are similar to those of PAN but have been less accurately measured.

As is evident from Figure 1, PAN in the upper troposphere has a lifetime of many months and thus can be transported over very long distances. Cold air masses containing PAN can

release NO_2 under warmer conditions. By removing NO_2 during its formation phases, transporting it in colder regions, and then rereleasing it in warmer environments, PAN provides an important mechanism for the global transport of NO_x thereby influencing processes of tropospheric ozone formation.

Detection and Measurement Methods

PANs are thermally unstable and are otherwise easily destroyed in contact with surfaces. Therefore, PAN measurements must be performed with minimum delay between sampling and analysis. PAN in the atmosphere has been measured by a variety of techniques. The first laboratory and atmospheric measurements of PAN were made using Fourier transform infrared spectroscopy. While extremely useful for confirmation of PAN, these techniques are best used under controlled laboratory conditions and when PAN concentrations are high. The most commonly used method for the routine measurement of PAN and its homologues has been with gas chromatography using electron capture detector (GC-ECD). Being a good electron absorber, PAN is sensitively detected by the ECD. A number of GC columns can be used to separate PAN from a complex atmospheric mixture of chemicals. Typically DB-210, SPB-1701, and Rtx-200-fused silica capillary columns (0.25–0.5 mm id, 5–30 m length, and $0.25 \mu\text{m}$ film thickness) or packed columns (3 mm id, 40 cm length) with 10% Carbowax 1000 on Supelcoport have been used to separate PAN from other atmospheric constituents. A direct 1–5 ml injection of air is generally adequate to measure PAN in urban and rural environments where PAN is nearly always present at a mixing ratio of $>0.1 \text{ ppb}$ (10^{-9} v/v ; nmol/mol ; ppbv).

In remote atmospheres, PAN concentrations can be extremely low and preconcentration of air samples is often necessary. A 100 ml sample of air freeze trapped at -140° C can provide a measurement sensitivity of 1 ppt (10^{-12} v/v ; pmol/mol ; pptv) in a GC-ECD system. In addition to PAN, a number of other important constituents can also be simultaneously measured. Because of their high sensitivity and easy availability, GC-ECD systems have been extensively used for the simultaneous detection of PANs, alkyl nitrates, and halogen tracers (C_2Cl_4) in airborne- and ground-based studies. Other techniques involving luminol chemiluminescent detection, pulsed discharge detection, and chemical ionization mass spectrometry (CIMS) have also been used on a more limited basis. All these techniques provide PAN measurements in a discreet mode and are relatively slow in response.

Recently, techniques have been developed for near continuous measurements of PAN and its homologues. In one widely accepted technique, PANs are thermally dissociated into acylperoxy radicals, which are made to react with I^- to produce a carboxylate ion that is unique for each parent species and is easily detected by mass spectrometry. Instruments based on TD-CIMS can measure a series of PANs with extremely fast response (1 s) and high sensitivity (10 ppt). Figure 2 shows a spectrogram of PANs from a sample of ambient air over Colorado. Fast response PAN detection is useful for airborne studies and for measurements of its deposition and flux over surfaces. Progress continues to be made to derive a global

climatology of PAN from satellite observations in the upper troposphere and lower stratosphere.

A major difficulty in the quantitative determination of PAN has been the preparation of accurate calibration standards. This largely arises from the fact that PAN is highly unstable and must be prepared in pure form utilizing secondary synthesis methods. In early years, PAN (and PPN) was synthesized by photolysis of alkyl nitrite in oxygen.

PANs produced by this method were quite impure and extensive preparative chromatography was required for purification. PAN was then analyzed by infrared spectroscopy using known IR band strengths typically at 793.9 and 1165 cm^{-1} . These methods were tedious and standards could be prepared only at very high concentrations. In recent years, better calibration methods have been devised. A widely used method utilizes the fact that highly pure PAN can be synthesized in a nonvolatile liquid matrix, such as *n*-tridecane, by nitration of peracetic acid. It is possible to keep a PAN/*n*-tridecane liquid mixture stable for a period of many weeks at dry ice ($-78^\circ C$) temperatures. For routine calibrations, a capillary diffusion tube (2 mm id) is filled with this PAN/*n*-tridecane solution and held at ice-water temperature ($0^\circ C$). Air flows over this tube at a known rate. A nylon filter is inserted in line to remove any traces of nitric acid. The PAN in the exit stream, typically 1–50 ppb, is measured by using a standard chemiluminescent NO_y detector. Trace quantities of CH_3ONO_2 and NO_2 are often present in the exiting air stream, but tests have shown that these impurities are quite small ($<5\%$). These standard mixtures can be further diluted with a dynamic dilution system to generate ppt level mixing ratios in air.

Atmospheric Concentrations

PAN and PPN have been extensively measured in urban and rural locations around the globe. Although PAN concentrations in excess of 200 ppb have been reported from Southern California from the 1960s, these must be considered extremely rare

occurrences. Since 1970, reported concentrations have never exceeded 60 ppb even under extreme polluted and stagnant conditions. **Figure 3** shows the daytime monthly mean and monthly maximum concentrations measured at Riverside in Southern California. A clear seasonal cycle with highest mixing ratios in summer and lowest in winter is seen. Monthly mean mixing ratios never exceeded 10 ppb.

The photochemical nature of PAN formation is also evident in its diurnal cycle with highest concentrations in the late afternoon (**Figure 4**). In rural locations, PAN mixing ratios rarely exceed 5 ppb and average values are in the vicinity of 1–3 ppb. There is no reliable information on the long-term trends in urban PAN, but there are indications that PAN levels have declined over the last four decades. In large part, this is attributable to the dramatic reductions that have been achieved in the emissions of hydrocarbons and NO_x from automobiles.

In remote atmospheres, PAN is nearly always present at sub-ppb levels. Its mixing ratios are generally higher in the middle and upper troposphere compared to the surface where it has a short lifetime. In many regions of the atmosphere, PAN is an important component of total reactive nitrogen often referred to as NO_y . **Figure 5** shows the partitioning of reactive nitrogen throughout the troposphere as measured over North America. PAN concentrations are lowest in the tropics and increase

Figure 3 Seasonal cycle of daytime PAN mixing ratios at Riverside, California.

rapidly toward higher latitudes. This is due to the greater abundance of precursors as well as the greater stability of PAN at the colder high latitudes. Although PAN concentrations can vary widely, it has been found to be globally ubiquitous.

Many PAN homologues have been detected in urban and rural environments. These are generally present only in the vicinity of the sources of their precursors and do not appear to play any significant role in global atmospheric chemistry. In urban atmospheres, PPN concentrations are typically 5–20% of PAN (Figure 4). However, as air masses are transported over long distances this ratio continues to decline. Measurements of APAN, PBzN, and MPAN are extremely sparse and often below detection limits. Limited data suggest that APAN and PiBN mixing ratios are 3–5% of PAN in urban areas. Upper limit PBzN measurements

suggest that its urban mixing ratios are in the sub-ppb range and almost never exceed 2 ppb. Similarly, MPAN, a product of biogenic hydrocarbon oxidation, has been measured at relatively low concentrations (10–350 ppt) in forested rural environments. Even when present at low concentrations, these PAN homologues can be used as unique photochemical tracers of a variety of anthropogenic and biogenic sources.

Biological/Toxic Effects

PANs are known to be eye irritants (lachrymators), phytotoxins, and bacterial mutagens. Potential phytotoxic episodes in which visible injury to susceptible plants occurs (e.g., pinto beans) are likely only when PAN concentration in excess of 15 ppb is sustained for several hours. Both the eye irritation potential and phytotoxicity of higher PAN homologues (e.g., PPN, PBzN) are substantially greater than that of PAN but their atmospheric concentrations are also much lower. A number of studies have been done on mice to assess the toxic affects of PAN. These studies used PAN concentrations that were often 10^2 – 10^3 times larger than what is typically encountered in polluted air. Based on existing data, it appears that the concentrations of PAN observed in urban atmospheres around the globe are too low to cause injury to human health. Long-term studies on the health effects of exposure to low concentrations of PAN and its homologues have not been performed. The most serious biological effects of PANs are of a phytotoxic nature resulting in injury to plants and vegetation.

Synopsis

This article reviews the sources and sinks of the most important organic sulfur that are released to the atmosphere mainly in the reduced form. The reduced sulfur compounds are analogous to organic oxygen compounds and consist of thiols (RSH), sulfides (RSR), and disulfides (RSSR) whereby dimethyl sulfide (DMS, CH_3SCH_3) is by far the most abundant and atmospherically important of all the reduced organic sulfur compounds. The atmospheric chemistry of DMS and its relevance is discussed at length.

Introduction

Sulfur plays an important role in both the tropospheric and stratospheric budgets of atmospheric gases and investigations of the atmospheric sulfur cycle have been a subject of intense scientific interest for many years. The reasons for the interest is the need to parametrize the contributions of atmospheric sulfur, which originate from both natural processes and anthropogenic activities, to environmental problems. The most important of these problems is an assessment of the magnitude of the involvement of the atmospheric chemistry of the organic sulfur compounds dimethyl sulfide (CH_3SCH_3 ; DMS) and dimethyl sulfoxide (CH_3SOCH_3 ; DMSO) in climate regulation or modification.

In industrialized regions such as the United States and most of the Europe, anthropogenic sulfur emissions (mainly comprising SO_2) exceed natural emissions by about one order of magnitude. On a global scale, biogenic emissions become important, with contributions to the sulfur budget of 15–20% and 50–60% in the Northern and Southern Hemispheres, respectively. Of the biogenic contribution, one compound, namely DMS, constitutes approximately 50% of the emissions. This article is restricted to the sources, sinks, and relevant gas-phase atmospheric interactions of the main organic sulfur compounds in the troposphere.

Organic Sulfur Compounds in the Atmosphere

The gas-phase chemistry of atmospheric sulfur involves nearly a score of compounds, representing sulfur valence states from -2 to $+6$. The important organic sulfur compounds that are released to the atmosphere are mainly in the reduced form. The common organic sulfur compounds are divalent and analogous to organic oxygen compounds such as alcohols and ethers: RSH, thiols; RSR, sulfides (thioethers); and RSSR, disulfides.

The names and structures of the organic sulfur compounds known to be involved in atmospheric sulfur chemistry are listed in [Figure 1](#). With the exception of hydroxymethanesulfonic acid and the highly reactive methanesulfenic and methanesulfinic acids, all of these compounds have been detected in the atmosphere. The more oxidized sulfur compounds are less volatile than the reduced

forms and as a result are partitioned to varying degrees into condensed phases. Other important inorganic sulfur compounds involved in the atmospheric sulfur cycle include hydrogen sulfide (H_2S), carbonyl sulfide (OCS), carbon disulfide (CS_2), sulfur dioxide (SO_2), and sulfuric acid (H_2SO_4). Although these compounds are not treated specifically in this article, the reader is strongly encouraged to consult the literature to obtain an insight into their role in atmospheric sulfur chemistry. The roles of sulfur dioxide and sulfuric acid in relation to organic sulfur atmospheric chemistry will become evident during the course of the article.

Over 20 thiols and nearly 40 sulfides/disulfides are known to be emitted into the atmosphere. The sources for most of these compounds are natural, but wood pulping, papermaking processes, and other industrial processes are also sources. Thioethers are widely used in various industries, for example, aryl, alkenyl, and alkyl thioethers are important synthetic reagents and intermediates in organic synthesis. They have been employed in the synthesis of novel biologically active compounds, polymer materials and used as extracting reagents. Because of the frequent unpleasant smells associated with them, even at very low levels, thioethers are mixed into liquefied petroleum gas and fuel cells as leakage sensor odorants. Alkyl thioethers, which can be found in garlic, are synthesized and used as forage additives. These uses may result in their potential release into the atmosphere. Alkyl thiols, dialkyl sulfides, and polysulfides are present in animals, animal manure, kerogens and are associated with sewage treatment plants and the wood pulping industry. Consequently, it is therefore not unreasonable to expect that some of the more volatile alkyl sulfides will be released to some extent to the atmosphere. Alkyl sulfides like diethyl sulfide ($\text{CH}_3\text{CH}_2\text{SCH}_2\text{CH}_3$, DES) and ethyl methyl sulfide ($\text{CH}_3\text{CH}_2\text{SCH}_3$, EMS) have both natural and industrial sources and have been detected over seaweeds fields, and in soil atmospheres.

Among all the organic sulfur compounds emitted into the atmosphere only methyl mercaptan, DMS, and dimethyl disulfide (DMDS) are of any real significance for atmospheric sulfur chemistry. Of these three organic sulfur compounds, it is now firmly established that DMS is by far the most important and abundant. The ranges in the literature estimations of the emission source strengths of the most

Figure 1 Structural and empirical formulas and names of the major important sulfur compounds in the atmospheric sulfur cycle. Commonly used abbreviations are also indicated.

important organic and inorganic sulfur compounds involved in the atmospheric sulfur cycle are listed in Table 1. The current 'best estimate' emission source strengths are also given.

DMS is a product of biological processes involving marine phytoplankton thus high concentrations of DMS are found in areas where microorganisms are abundant, however, the amounts released vary with species and the stage of their life cycle. Seawater is found to be highly supersaturated with respect to atmospheric levels of DMS, which indicates a net flux of this gas from the ocean to the atmosphere of the order of 15–45 Tg (S) per year. The fluxes to the atmosphere are dependent not only on concentration but also on wind speed,

which makes determination of fluxes difficult and accounts for the large variation in reported values. With the increasing number and sophistication of field studies somewhat lower DMS fluxes in the range 10–20 Tg (S) per year are now more favored. Detailed seasonal maps of DMS in seawater in the world's oceans are available, and highlight the biological origin of the compound. Some DMS in seawater is probably oxidized to DMSO, however, since DMSO is much more soluble than DMS it is unlikely to be released from seawater in any significant amounts.

DMS is estimated to account for approximately 50–60% of the total natural sulfur gas released to the atmosphere. Numerous measurements have been made and continue to

Table 1 Ranges of estimated global sulfur emissions as reported in the recent literature

Substance	Total emission rate (Tg (S) per year)	
	Literature ranges	Current best estimate

be performed on the atmospheric concentration of DMS. The atmospheric concentration of DMS is highly variable. In the free troposphere, concentrations are very low, probably <3 ppt. In the marine boundary layer (MBL), it varies from <10 ppt in polluted air to 50–100 ppt over oligotrophic waters and can be as high as 1 ppb in coastal and upwelling waters. At sea surface level the global DMS average is of the order of 100 ppt. In clean marine conditions, atmospheric DMS concentrations typically exhibit minima in the afternoon and maxima at night due to daytime oxidation by the OH radical. Under polluted conditions the diurnal cycle can be affected by oxidation of DMS at night by the NO₃ radical. Atmospheric measurements of DMSO are not as frequent as those for DMS because of measurement difficulties. Mixing ratios of DMSO have been measured in the ranges 0.4–5.8 ppt in the southern Indian Ocean, 0.4–57 ppt in coastal Antarctica, and 0.02–10.1 ppt over northeastern Crete.

There are presently no good estimations of the emission strengths of both methyl mercaptan and DMDS. Methyl mercaptan is probably only of importance in the vicinity of industrial sources and reported mixing ratios over the surface ocean and in tropical forests are typically <5 ppt. No reliable measurements exist on the atmospheric concentrations of DMDS. Owing to its high atmospheric reactivity, atmospheric concentrations of DMDS are very low and of importance only in the proximity of the source. Opinions are currently divided concerning the importance of the contribution of DMDS to the atmospheric sulfur cycle and budget.

Chemical Transformation Mechanisms in the Atmosphere

The atmospheric chemistry of DMS and the other organic sulfur compounds is very complex. However, common intermediates are involved in the atmospheric oxidation processes for all three of the most common organic sulfur compounds – CH₃SH, DMS, and DMDS. Several reviews listed in the literature give good detailed accounts of laboratory kinetic and product investigations on the atmospheric reactions of CH₃SH, DMS, and DMDS.

Main Oxidants

For all the compounds, it is generally accepted that reaction with the OH radical is the most important daytime initiator of the oxidation process. During the night and under highly polluted conditions, reactions with NO₃ radicals will be of importance. Concurrent measurements of OH and NO₃ radicals, for example, during a campaign over the northeastern coast of Crete indicated that the NO₃ levels could explain most of the observed diurnal variation of DMS. Similarly, measurements of DMS and NO₃ radicals in a polluted marine environment off the New England Coast indicated that, depending on NO₃ mixing ratios, between 65 and 90% of the DMS oxidation was due to NO₃. The area over which DMS oxidation by NO₃ was at least as strong as by OH was estimated to extend as far as 3000 km from the coastal anthropogenic NO_x sources. Under pristine background marine conditions with very low NO_x, reactions with NO₃ are relatively unimportant.

Models of global sulfur chemistry have been interpreted as indicating that DMS sulfur chemistry is too rapid to be accounted for entirely by known sink reactions with OH and NO₃ radicals. It has been suggested that reactions with halogens or halogen oxides could be a hitherto neglected sink for DMS in the MBL. Evidence is currently emerging that chlorine and bromine chemistry is more important in the troposphere than had been previously thought, although more field experiments are needed for definite validation. In recent field campaigns, midcontinental observations of the chlorine atom precursor nitryl chloride (NOCl) have been reported at a distance of 1400 km from the nearest coastline. It has also been suggested that a significant fraction of tropospheric chlorine atoms may arise directly from anthropogenic pollutants. The BrO radical has now been detected in many field campaigns in both polluted and nonpolluted marine environments and in some environments the oxidation of DMS by BrO has been found to take place at a comparable rate to oxidation by OH. In summary, the current evidence from field campaigns supports that it is highly probable that Cl atoms and BrO radicals are quite important oxidants for DMS under certain conditions and reactions of DMS with these oxidants need to be included in models of DMS tropospheric chemistry. Table 2 lists the typical atmospheric concentrations of potential oxidants for DMS, their rate coefficients with DMS, and remarks on their potential importance based on these parameters.

Initiating Oxidation Steps

The DMS–OH reaction is now known to proceed via both O₂-independent and O₂-dependent pathways (eqns [I]–[III]).

The O₂-independent pathway dominates at room temperature and involves hydrogen abstraction. The O₂-dependent

DMS, Dimethyl sulfide.

^aThe lifetime τ_{DMS} is defined as $1/k[\text{reactant}]$ where k is the rate coefficient (cubic centimeter per molecule per second) for the reaction of the reactant with DMS and $[\text{reactant}]$ is the typical atmospheric concentration (molecule cm^{-3}) of the species.^bConcentration is very variable.^cProbably most important in the Arctic, but recent field measurements indicate a possible global importance for BrO; ongoing field/satellite measurements should resolve this issue in the near future.

pathway involves formation of an adduct $((\text{CH}_3)_2\text{S}-\text{OH})$ with a binding energy of $\sim 45 \text{ kJ mol}^{-1}$. The fate of the adduct is reaction with O_2 in competition with decomposition back to reactants. The adduct lifetime is strongly temperature dependent and lowering the temperature favors the addition over the abstraction channel. As discussed below, DMSO is now known to be a major product (over 50%) of the reaction of the adduct with O_2 . The mechanism of OH reaction with methyl mercaptan (CH_3SH) ($k_{\text{OH}}(298 \text{ K}) = 3.3 \times 10^{-11} \text{ cm}^3 \text{ per molecule per second}$) is unclear; however, it appears that the reaction leads to CH_3S radical formation. Although a direct hydrogen atom abstraction pathway is operative, the observation of a negative temperature dependence supports formation of adducts. Formation of an OH adduct ($\text{CH}_3\text{S}(\text{OH})\text{H}$) that rapidly eliminates H_2O can therefore not be excluded (eqns [IV] and [V]).

The kinetics of the reaction of OH with DMDS ($k_{\text{OH}}(298 \text{ K}) = 2.3 \times 10^{-10} \text{ cm}^3 \text{ per molecule per second}$) also shows a negative temperature dependence, which again suggests that the mechanism involves complex formation. Formation of CH_3S and CH_3SOH has been observed, however, a measured yield of 30% for CH_3S indicates that other pathways leading to CH_3 and CH_3SSOH are also operative (eqns [VI] and [VII]).

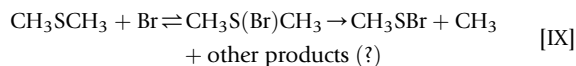

The available evidence suggests that reaction of DMS with NO_3 proceeds initially by NO_3 addition to the sulfur atom followed by hydrogen intramolecular transfer, i.e., an overall hydrogen abstraction reaction (eqn [VIII]).

For the reactions of NO_3 with CH_3SH ($k_{\text{NO}_3}(298 \text{ K}) = 9.2 \times 10^{-13} \text{ cubic centimeter per molecule per second}$) and DMDS ($k_{\text{NO}_3}(298 \text{ K}) = 7 \times 10^{-13} \text{ cm}^3 \text{ per molecule per second}$), a mechanism involving initial addition of NO_3 to the sulfur atom followed by rearrangement or fragmentation of the adduct has been inferred from the scant information that is available. Because of the fast reaction of OH radicals with DMDS, reaction between NO_3 and DMDS is probably of only marginal importance in the atmosphere.

There is increasing evidence that reactive halogen chemistry involving X and XO, where X = Cl, Br, or I, plays an important role in tropospheric chemistry in the MBL. The role of halogen species, especially BrO and Cl, in the oxidation of DMS is still unclear and may be very regionally dependent, as demonstrated in Table 2. For the reaction of Cl with DMS, a direct hydrogen transfer pathway leading to formation of HCl and CH_3SCH_2 radicals is operative along with an adduct-forming channel. The products of the adduct-forming channel have not yet been characterized. The reaction of Br with DMS

proceeds via reversible adduct formation but there also appears to be an adduct decomposition channel leading to formation of CH_3SBr and CH_3 radicals.

The overall reaction rate is too slow (see Table 2) for the process to be of any significance in the atmosphere. The reaction of iodine atoms with DMS is negligibly slow and also not important.

The kinetics of the reactions of ClO , BrO , and IO with DMS have been measured and the rate coefficients take the order $\text{BrO} > \text{ClO} \sim \text{IO}$. All of the reactions are thought to result in oxidation of DMS to DMSO and release of the halogen atom. Based on the available kinetic data, atmospheric model calculations indicate that oxidation by BrO can be a relevant sink of DMS, which could account during daytime for 24–38% loss of DMS. Very recent kinetic data indicate that the reaction of BrO with DMSO at high pressure may be significantly faster than previously determined, which would further enhance the importance of BrO . This remains to be validated. In addition, the reaction of BrO with DMS can promote $\text{O}_3 \rightarrow \text{O}_2$ conversion through the sequence of eqns ([X] and [XI]) where DMS is oxidized and no BrO is lost.

Thus, BrO can be an important sink of DMS in the presence of O_3 , and at the time of writing field campaigns are in progress to quantify the possible contribution to the DMS budget.

Reactions of Other Organic Sulfur Compounds with Oxidants

In comparison to the many studies performed on the reactions of CH_3SH , DMS, and DMDS, there have been very few studies on the atmospheric chemistry of other organic sulfur compounds. There have been several room-temperature kinetic studies of the gas-phase reactions of OH radicals with the dialkyl sulfides, DES and EMS, and the cyclic compounds, tetrahydrothiophene and thiophene. The measured rate coefficients for reactions of OH with both DES and EMS show an O_2 partial pressure dependence and the experimental observations are consistent, a four-step mechanism involving a direct H-atom abstraction channel, and a reversible OH addition channel forming an OHSR_2 adduct, which can react with molecular oxygen has been postulated to explain the complex kinetics of the reaction of DMS with OH radicals in the presence of oxygen.

High yields of SO_2 are observed in the reaction systems indicating that the H-atom abstraction channel is the most important pathway for the reactions of OH radicals with both DES and EMS. From kinetic investigations, it has been estimated under atmospheric conditions approximately 73 and 76% of the reactions of OH with DES and EMS, respectively will proceed via the abstraction channel. The reactions form mainly RSCHCH_3 radicals. These react with molecular oxygen to form alkylthio peroxy radicals ($\text{CH}_3\text{CH}(\text{OO}\cdot)\text{SR}$), which are further converted to alkylthio alkoxy radicals ($\text{CH}_3\text{CH}(\text{O}\cdot)\text{SR}$)

the major fate of which is decomposition to give an aldehyde and an alkyl thiyl radical (RS) as discussed in detail for DMS below. The subsequent reactions of the alkyl thiyl radicals will lead to a large extent to the formation of SO_2 and an aldehyde. The yields of aldehydes and SO_2 measured in the product studies support that reaction channels other than decomposition are probably also operative for the alkylthio alkoxy radicals. Reactions of OH with DES and EMS with O_2 may lead to formation of thioesters: s-ethyl thioacetate ($\text{CH}_3\text{CH}_2\text{SC}(\text{O})\text{CH}_3$), s-methyl thioacetate ($\text{CH}_3\text{SC}(\text{O})\text{CH}_3$), and s-ethyl thioformate ($\text{CH}_3\text{CH}_2\text{SCHO}$). In contrast to the chemistry of the alkoxy radicals formed in the reaction of OH with DMS (see below), the alkoxy radicals $\text{CH}_3\text{CH}_2\text{SCH}(\text{O}\cdot)\text{CH}_3$ and $\text{CH}_3\text{CH}_2\text{SCH}_2(\text{O}\cdot)$ formed in the $\text{OH} + \text{DES}$ and EMS reactions, respectively, could isomerize by a 1,5-H shift through a six-member transition state. The sulfur and carbon balances in gas-phase product studies of the oxidation of dialkyl sulfides are currently only of the order of 50%.

Room-temperature rate coefficients have been reported for the gas-phase reactions of Cl atoms, DES, EMS, di-n-propyl sulfide, and di-n-butyl sulfide. A very slow rate coefficient of $2.77 \times 10^{-19} \text{ cm}^3$ per molecule per second has been reported for the reaction O_3 with DES and it is probable that the reactions of O_3 with other alkyl sulfides are equally slow and of no atmospheric importance. Apart from DMS, there do not appear to have been any kinetic studies of the gas-phase reactions of NO_3 radicals or halogen oxides (OX , $\text{X} = \text{Cl}, \text{Br}, \text{I}$) with alkyl sulfides. Reactions of NO_3 and BrO radicals with the alkyl sulfides are likely to be of the same order of magnitude or faster than the corresponding reactions of the radicals with DMS and thus of potential importance as atmospheric sinks for the compounds.

Observed DMS Oxidation Products and Possible Formation Pathways

Although the rate coefficients for the initiation reactions of organic sulfur compounds are reasonably well established, the reactions responsible for the observed products and their yields are not always clear. Product information has been obtained using absolute methods, but much of the information stems from studies in so-called photochemical reactors. Many of these product studies have employed highly variable NO_x levels, and the chemistry that occurs in these high NO_x systems can be very different from that occurring in the marine atmosphere where the NO_x levels are generally very low. Consequently, there is a large variation in the yields of the products reported in the literature and it is still not possible to make reliable quantitative predictions of the distribution of DMS oxidation products for specific sets of atmospheric conditions.

In laboratory photoreactor studies at room temperature, SO_2 , methanesulfonic acid (MSA), DMSO, dimethyl sulfone (DMSO_2), and methylsulfonyl peroxyxynitrate (MSPN ; $\text{CH}_3\text{SO}_2\text{OONO}_2$) have been observed as products of both the OH and NO_3 radical-initiated oxidation of DMS. In the reaction of NO_3 with DMS, unity yield of HNO_3 is also observed, formed via a hydrogen-atom abstraction reaction from one of the CH_3 entities. Formation of methanesulfinic acid (MSIA) in

significant yield has been reported very recently for OH + DMS. Both laboratory and field observations support that SO₂ is a major oxidation product of DMS oxidation, and recent photoreactor studies have demonstrated that it may be formed via both the addition and abstraction channels in OH + DMS. Under NO_x conditions approaching those of the atmosphere, SO₂ molar yields of 70–80% have been reported for photoreactor experiments on OH + DMS. Similar yields have been deduced from field measurements of DMS and its products. Apart from gas-phase oxidation with OH radicals to form H₂SO₄(g), the main fate of SO₂ is uptake in the liquid aerosol (condensed phase) and oxidation of H₂SO₄(l).

As indicated earlier, results from room-temperature laboratory end-product studies show that DMSO is a major product of the addition pathway in the OH + DMS reaction. The absolute molar yield is still uncertain, but it is of the order of 50–70% and may be higher. In the gas phase, DMSO is known to be oxidized rapidly by OH radicals ($k_{\text{OH}}(298\text{ K}) \sim 10^{10}\text{ cm}^3\text{ per molecule per second}$). The results from OH + DMSO product investigations are contradictory. DMSO₂, SO₂, and MSA have been observed as products in photoreactor studies; however, there are considerable discrepancies in the yields and secondary chemistry is thought to strongly influence the product distribution in such studies. In a recent time-resolved tunable diode laser spectroscopy study on the OH + DMSO reaction, CH₃ radicals were detected in near unity yield at low pressure. This supports a mechanism in which the main reaction pathway is the formation of CH₃ radicals with methanesulfinic acid as coproduct. At this writing, photoreactor experiments using ion chromatography to detect MSIA have been reported that substantiate the tunable diode laser spectroscopy study.

The only product observed in the reaction of NO₃ with DMSO is DMSO₂. DMSO and DMSO₂ have been identified in field measurements in the gas/aerosol phase and also in rain-water samples. The fate of these compounds is poorly understood with regard to their removal by heterogeneous processes or by deposition. There is evidence that in the condensed phase DMSO is oxidized initially to MSIA, which is then further oxidized to MSA.

Carbonyl sulfide (OCS) has been detected in chamber product studies of the OH-initiated oxidation of DMS under low NO_x conditions. A formation yield of $0.7 \pm 0.2\%$ S was reported. The mechanism of formation is not known. Although the OCS yield is low, because of the relatively high global DMS source strength (15–45 Tg (S) per year), the result suggests that the oxidation of DMS could represent a substantial source of atmospheric OCS, contributing 0.10–0.28 Tg (OCS) per year.

In summary, although the major products of the OH- and NO₃-initiated oxidation are known, detailed quantitative information on their distribution is not yet available, particularly with regard to the effects of temperature and variable O₃ and NO_x concentrations. More information on the fate of DMSO is important because at high latitudes the O₂-dependent addition branch of the OH + DMS reaction forming DMSO in high yield dominates the overall DMS reactivity. Thus with decreasing temperature DMSO chemistry, both gas and liquid phases (DMSO is highly water soluble), will increasingly control the branching ratio for SO₂, SO₄²⁻, and acid formation (MSA and MSIA). Thus an exact knowledge of

the formation yield of DMSO with temperature is an important parameter in atmospheric organic sulfur chemistry.

Reaction Pathways Leading to Products

As indicated above, generation of the CH₃SCH₂ radical is an important pathway for the Cl-, OH-, and NO₃-initiated oxidation of DMS (eqn [XII]). In the atmosphere, the CH₃SCH₂ radical will add O₂ to form the peroxy radical CH₃SCH₂OO (eqn [XIII]).

It is known that reaction with NO will produce NO₂, CH₃S, and formaldehyde (eqn [XIV]).

It has been suggested that in the remote MBL, where NO_x levels are low (typically 2–8 ppt), the main daytime removal process for CH₃SCH₂OO could be reaction with HO₂ to form a hydroperoxide (eqn [XV]).

It is argued that if the removal of this hydroperoxide by photolysis and reaction with OH (see Figure 2 for pathways) is similar in magnitude to that of CH₃OOH, then CH₃SCH₂OOH may be a significant reservoir species for sulfur in the remote MBL. As shown in Figure 2, similar pathways may also exist for other oxidized forms of CH₃SCH₂OOH. This present hypothesis remains to be verified by either field observations or laboratory experiments. It is interesting to note that if the surface deposition and/or washout and rainout processes of CH₃SCH₂OOH and its oxidized forms are significant, which is probably the case, then these processes represent a potential short circuit for DMS atmospheric chemistry, preventing formation of the gas-phase oxidized forms.

It is now well established that CH₃S is an important intermediate in the oxidation of DMS and also of CH₃SH. Despite the key role that the CH₃S radical plays in atmospheric sulfur chemistry, the reactions that convert it to S(vi) end products, H₂SO₄ and CH₃SO₃H (MSA), are poorly understood. A weakly bound CH₃S–O₂ adduct is known to exist and it is quite probable that CH₃SO_x–O₂ adducts ($x = 1, 2$) may also be important. At the time of writing, the available laboratory data indicate that reaction of O₃ with CH₃S will probably be a dominant removal pathway for this species in the atmosphere and that NO₂ could also play a role under polluted conditions. Reactions of O₃ and NO₂ with CH₃SO_x ($x = 1$ or 2) may also be important. Table 3 compares the first-order loss rates for reactions of CH₃S and CH₃SO_x ($x = 1$ or 2) with O₂, O₃, and NO₂ for different O₃ and NO₂ levels.

The products of these reactions are not clear, but the available evidence supports the yield of CH₃SO₂ being substantial. It is often argued that thermal decomposition of CH₃SO₂ radical to CH₃ and SO₂ is the most important reaction in determining the formation of SO₂ in DMS oxidation. Important competing steps will be reaction with O₂ or O₃, which will

Figure 2 Possible atmospheric reactions of the $\text{CH}_3\text{SCH}_2\text{OO}$ radical and its oxygenated analogs $(\text{CH}_3\text{S}(\text{O})_x\text{CH}_2\text{OO}, x = 1 \text{ or } 2)$. The large parentheses around the $\text{S}=\text{O}$ bonds denote two different initial reactants and subsequent products, i.e., a compound with an $\text{S}=\text{O}$ entity and another with an SO_2 entity.

result in the formation of $\text{CH}_3\text{S}(\text{O}_2)\text{OO}$ and CH_3SO_3 . Since the majority of SO_2 is oxidized in the condensed phase, the thermal decomposition will result in a low yield of $\text{H}_2\text{SO}_4(\text{g})$; however, unity conversion of CH_3S to nonsea-salt sulfate would occur. Thermal decomposition of CH_3SO_3 to CH_3 and SO_3 would lead to a high yield of $\text{H}_2\text{SO}_4(\text{g})$ via further reaction of SO_3 with water. However, at the time of writing it is thought that bimolecular reaction with hydrogen-containing species to form MSA dominates. $\text{CH}_3\text{S}(\text{O}_2)\text{OO}$ can add NO_2 to form a short-lived peroxyxynitrate, but further reaction to generate MSA will also occur.

The unimolecular decomposition rates of CH_3SO_x radicals and their O_2 adducts are expected to be strongly temperature dependent. Competition between the thermal decomposition of these adducts and their bimolecular reactions with atmospheric species is the most probable reason for much of the

variation not only in field observations of DMS oxidation products but also in the variations of products reported in laboratory studies.

Representation of DMS Oxidation in Models

Accurate and detailed models of all aspects of the atmospheric chemistry of DMS are necessary to assess any role that DMS may potentially play in the formation of new cloud condensation nuclei (CCN) formation in oceanic regions and thus climate regulation. As evidenced in this article the gas-phase chemistry of DMS is highly complex and uncertain in many aspects and in addition the nucleation ability of DMS-derived sulfuric acid in the MBL is controversial and much debated in the scientific literature. Many DMS oxidation mechanisms have been

Table 3 Comparison of the first-order loss rates ($k[A]$) for the reaction of CH_3SO_x ($x=1-2$) radicals with O_2 , O_3 , and NO_2 at 298 K under various atmospheric conditions

^aThe rate coefficient is for the reaction $\text{CH}_3\text{S} + \text{O}_2$ going to products other than CH_3SOO . The upper limit is not corrected for the $\text{CH}_3\text{S} + \text{O}_2 \leftrightarrow \text{CH}_3\text{SOO}$ equilibrium.

^bThe rate coefficient is estimated, only the reaction $\text{CH}_3\text{S} + \text{O}_2$ going to products other than $\text{CH}_3\text{S} + \text{O}_2 \leftrightarrow \text{CH}_3\text{SOO}$ is considered. The rate is not corrected for the $\text{CH}_3\text{SO}_x + \text{O}_2 \leftrightarrow \text{CH}_3\text{SO}_x\text{OO}$ equilibrium.

formulated from the available experimental evidence for use in various types of atmospheric models used to assess the role of DMS in climate. The schemes range from very detailed descriptions of the DMS oxidation with up to 65 reactions to a very simple scheme with only six reactions suitable for global modeling. The Master Chemical Mechanism (<http://mcm.leeds.ac.uk/MCM/>) is a near-explicit chemical mechanism, which describes the detailed gas-phase chemical processes involved in the tropospheric degradation of a series of primary emitted volatile organic compounds (VOCs). Currently, the degradation of methane and 142 nonmethane VOCs is represented and recently a very simplified DMS oxidation mechanism has been added. There have been several assessments of the various mechanisms with respect to their capability of predicting observed end products of the DMS oxidation at climatologically different locations in the remote MBL. In the most recent intercomparison of seven commonly used DMS oxidation chemical mechanisms for the remote MBL, the conclusion was reached that several uncertainties limiting our understanding of atmospheric oxidation of DMS with implications for climate still exist.

Important Atmospheric Interactions of DMS

Aerosols in the 0.001–10 μm size range play a crucial role in regulating climate since they scatter and absorb radiation in the solar and thermal infrared ranges, which modifies the Earth's radiation budget. A significant fraction of the tropospheric aerosol mass in the submicrometer-size particles is estimated to be derived from homogeneous and in-cloud oxidation of gaseous sulfur compounds, which are both of anthropogenic and biogenic origin. There are three main sources of aerosol in the remote MBL: sea-salt and nonsea-salt sources, and entrainment of free tropospheric aerosol. The SO_2 produced from DMS oxidation is the predominant source of *in situ*

nonsea-salt sulfate. SO_2 is oxidized to H_2SO_4 in the gas phase by reaction with OH and in sea-salt aerosols and cloud droplets. H_2SO_4 contributes either to aerosol growth or to the formation of new sulfate particles. The formation and subsequent growth of small particles can affect climate via direct scattering and absorption of solar radiation (direct effect), and by modifying the frequency, lifetime, and optical properties of clouds (indirect effect).

According to the CLAW hypothesis, the aerosol formation stemming from the degradation of DMS could play an important role in the radiation budget and possibly climate regulation. In the hypothesis, long-term climate is seen as part of a feedback loop in which warmer temperatures would increase phytoplanktonic activity in the oceans, which in turn would increase emissions of DMS. It is suggested that higher DMS concentrations in the atmosphere would increase sulfate containing CCN and thus cloudiness and albedo and lead to lower temperatures. Although the CLAW hypothesis is an interesting and once very popular vision of the biological mediation in global climate, evidence from ice cores has yet to offer convincing proof for this concept of climate control. In addition many studies are now highlighting significant nonlinearity in DMS aerosol–cloud interactions.

Considering the potential importance of DMS in the regulation of the Earth's climate, there have been relatively few laboratory investigations of DMS photooxidation systems aimed at quantifying the contribution of DMS-derived nonsea-salt sulfate to CCN. Model studies of global SO_2 indicate that there may be as yet unaccounted oxidants involved in the DMS oxidation. The Intergovernmental Panel on Climate Change (1995) has classified the coupling between DMS and aerosols as an important component of the planetary climate system that needs to be understood in detail.

The evaluation of the role of DMS in climate regulation has been complicated recently by two important findings. First, the conventional view has generally been that nonsea-salt sulfate is

Figure 3 Simplified diagram of the processes involved in the degradation of DMS in the marine atmosphere. The dotted lines represent processes where considerable uncertainty still exists concerning the branching ratios and/or kinetics and the question marks signify that either the existence or the importance of the channel is not known.

Figure 4 Simplified chemical mechanism for the atmospheric gas-phase reaction of OH radicals with DMS.

the primary source of CCN in the remote MBL and that sea salt contributes little to this CCN population. However, recent evidence suggests that the contribution from sea salt to CCN can often be quite substantial and under conditions of high wind speed may even dominate, and also that scavenging of SO₂ and H₂SO₄ by sea-salt aerosol is significant. These findings show that nonsea-salt sulfate and sea-salt aerosols cannot be considered as distinct populations and imply that any predicted climate changes based solely upon changes in nonsea-salt sulfate CCN concentrations are likely to be substantially overstated. Second, a recent comprehensive, geographically resolved inventory of ship emissions has shown that in large sections of the Northern Hemisphere, and in some regions of the Southern Hemisphere, anthropogenic sulfur emissions from ships are comparable to biogenic DMS emissions, the dominant source of sulfur from the ocean. Ship emissions have the potential to affect air quality in many coastal and port regions along heavily traveled international trade routes. The results suggest that emissions of sulfur and particulate matter from the international shipping industry need to be considered in the study of marine and coastal atmospheres.

As evidenced by the material presented here, further progress in the elucidation of the DMS oxidation mechanism and its implications for the Earth's climate will require both further advances in field studies and detailed kinetic studies combined with modeling of the field data (Figures 3 and 4).

Volatile Organic Compounds Overview: Anthropogenic

RG Derwent, rdscientific, Newbury, UK

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

The term anthropogenic volatile organic compounds (VOCs) refers to those organic compounds other than methane that arise from human activities and are capable of producing photochemical oxidants such as ozone by atmospheric chemical reactions with nitrogen oxides in the presence of sunlight. VOCs are an important class of air pollutants commonly found in the atmosphere at ground level in all urban and industrial centers. There are many hundreds to thousands of compounds, which come within the category of VOCs. Not all VOCs contribute equally strongly to photochemical oxidant formation. Some VOCs show a high propensity to form oxidants whilst others are largely unreactive.

Definition

The term anthropogenic volatile organic compounds (VOCs) refers to those organic compounds other than methane that arise from human activities and are capable of producing photochemical oxidants such as ozone by atmospheric chemical reactions with nitrogen oxides in the presence of sunlight.

Background

The role and importance in atmospheric chemistry of VOCs produced by human activities was established about 60 years ago by Haagen-Smit in his pioneering studies of Los Angeles smog (Haagen-Smit et al., 1953). He identified the key role of hydrocarbon (HC) oxidation, in the presence of sunlight and oxides of nitrogen (NO_x), as a photochemical source of ozone (O_3) and other oxidants. Detailed understanding of the mechanism of photochemical smog formation has developed since then through the combination of smog chamber, laboratory chemical kinetics, field experiment, air quality monitoring, and computer modeling studies.

Since these early pioneering studies in Los Angeles, photochemical smog and the elevated ozone levels associated with it, have subsequently been detected in almost all of the world's major urban and industrial centers, at levels which exceed internationally agreed criteria set to protect human health (World Health Organisation, 2006). Despite the importance given now to VOCs, their routine measurement in the atmosphere has only recently become commonplace. Furthermore, there are few detailed emission inventories for the major urban and industrial centers for which anthropogenic VOC emissions are fully resolved by species.

Properties of VOCs

VOCs are an important class of air pollutants commonly found in the atmosphere at ground level in all urban and industrial centers. There are many hundreds to thousands of compounds, which come within the category of VOCs and the situation is yet further complicated by different definitions and nomenclature. Strictly speaking, the term VOC refers to those organic

compounds, which are present in the atmosphere as gases but which under normal conditions of temperature and pressure would be liquids or solids. A VOC is by definition, an organic compound whose vapor pressure at say 20 °C is less than 760 torr (101.3 kPa) and greater than 1 torr (0.13 kPa). Many common and important organic compounds would be ruled out of consideration if these upper and lower limits were strictly adhered to.

Here, this strict definition is not applied and the term VOC is taken to mean any carbon-containing compound found in the atmosphere, excluding elemental carbon, carbon monoxide, and carbon dioxide. This definition is deliberately wide and encompasses both gaseous carbon-containing compounds and those similar compounds adsorbed onto the surface of atmospheric suspended particulate matter. The definition here includes substituted organic compounds so that oxygenated, chlorinated, and sulfur-containing organic compounds would come under the definition of VOCs. Some of the most strongly and widely emitted VOCs are listed in Table 1. Although this top 50 list has been compiled using emissions data for the United Kingdom, the major VOC sources, such as motor vehicle exhausts and solvent usage, are common across much of northwest Europe and so the list has a wider relevance than just to the United Kingdom.

Other terms used to represent VOCs are HCs, reactive organic gases (ROGs), and nonmethane VOCs. The use of common names for the organic compounds is preferred here since these are more readily understood by industry and more commonly used in the air pollution literature. IUPAC names are, however, provided in all cases in Table 1 where they differ significantly from the common names.

VOCs play a crucial role in ground level photochemical oxidant formation since they control the rate of oxidant production in the presence of sunlight in those areas where NO_x levels are sufficient to maintain ozone production. The contribution that organic compounds make to the exceedance of environmental criteria for ozone is now widely recognized. Long-range transboundary transport of ozone is an important feature of the problem. Organic compounds come within the scope of the Geneva Protocol to the United Nations Economic Commission for Europe International Convention on Long-range Transboundary Air Pollution (http://www.unece.org/env/lrtap/vola_h1.html). Ground level ozone is of concern

Table 1 Common names, IUPAC names, percentage emission by mass, and POCPs of the 50 most prolifically emitted VOCs in the United Kingdom

Common name	IUPAC name	Percentage emission by mass, %	POCP
<i>n</i> -butane	butane	8.9	31
ethanol		7.4	34
ethane		5.0	8
propane		3.9	14
toluene	methylbenzene	3.6	44
<i>n</i> -pentane	pentane	3.5	40
<i>i</i> -pentane	2-methylbutane	3.2	34
ethylene	ethene	2.8	100
<i>n</i> -hexane	hexane	2.6	40
methanol		2.0	13
<i>m</i> -xylene	1,3-dimethylbenzene	2.0	86
trichloroethene		2.0	29
2-methylpropane		1.9	28
formaldehyde	methanal	1.7	46
acetone	propanone	1.6	6
<i>n</i> -heptane	heptane	1.4	35
ethylbenzene		1.3	46
propylene	propene	1.2	117
<i>n</i> -octane	octane	1.2	34
benzene		1.1	10
methylethylketone	2-butanone	1.1	32
<i>o</i> -xylene	1,2-dimethylbenzene	1.0	78
1,2,4-trimethylbenzene		1.0	110
dichloromethane		1.0	3
butyl acetate		1.0	26
acetylene	ethyne	0.9	7
<i>p</i> -Xylene	1,4-dimethylbenzene	0.9	72
2-propanol		0.8	18
2-methylpropene		0.8	63
ethyl acetate		0.8	19
<i>n</i> -decane	decane	0.8	36
tetrachloroethene		0.5	1
4-methyl-2-pentanone		0.5	52
2-butene		0.5	113
1-butanol		0.4	52
<i>n</i> -nonane	nonane	0.4	34
2-butoxyethanol		0.4	45
1,3,5-trimethylbenzene		0.4	107
acetaldehyde	ethanal	0.4	55
1,3-butadiene		0.4	89
2-methylpentane		0.4	41
methyl acetate		0.4	7
undecane		0.3	36
2-pentene		0.3	111
1-propanol		0.3	48
1-methoxy-2-propanol		0.3	34
1,2,3-trimethylbenzene		0.3	105
methylethylbenzene		0.3	73
2-methylhexane		0.3	32
3-methylpentane		0.2	37

Percentage emissions by mass taken from <http://naei.defra.gov.uk/>.
 POCPs taken from Derwent, R.G., Jenkin, M.E., Passant, N.R., Pilling, M.J., 2007. Environmental Science Policy 10, 445–453.

not only with respect to human health but also because of its effects on crops, plants, and trees. Elevated ozone concentrations during summertime photochemical pollution episodes may exceed environmental criteria set to protect human health and natural ecosystems. It is these concerns, which led to the formulation of the Geneva Protocol and which underpin the reductions in emissions and control actions, which it stipulates.

Not all VOCs contribute equally strongly to photochemical oxidant formation. Some VOCs are highly reactive and show a high propensity to form oxidants. Others are largely unreactive and make little or no contribution to ground level ozone formation. Reactivity scales have been constructed to provide an indication of each VOCs' propensity to contribute to ground level ozone formation. One such scale is the photochemical ozone creation potential (POCP) scale (Derwent et al., 2007). POCPs are expressed relative to ethylene (=100) and give the formation potential of each VOC on a mass emitted basis. The POCPs of the top 50 most strongly and widely emitted VOCs are listed in Table 1. POCPs range from 1 for the most unreactive chlorinated solvent, tetrachloroethylene, a widely used dry cleaning agent to 117 for the highly reactive propylene, an important component of motor vehicle exhaust. Representatives can be found in Table 1 of some of the more important classes of organic compounds including alkanes, alkenes, aromatic, and oxygenated organic species.

Sources of VOCs

There are a wide range of sources in urban and industrial areas that give rise to VOC emissions. Motor vehicle traffic is an important source of VOCs, which arise from the exhaust and evaporative emissions of petrol-engined road vehicles. Motor spirit has a high vapor pressure and so emissions of VOCs can occur from moving and stationary vehicles, from the petrol stations when vehicle and storage tanks are being filled, and from the petrol distribution chain that supplies petrol station forecourts. VOC emissions arise from oil refineries and industrial facilities that produce bulk organic chemicals. VOCs are often valuable solvents and are widely used in the home and in industry in paints, lacquers, varnishes, inks, and degreasing agents (<http://www.ceip.at/>). Some of the most widely emitted VOC species are listed in Table 1, together with their fractional emission rates and POCPs.

To reduce exposure levels to elevated ozone levels, actions have been taken to control photochemical ozone formation in many countries across the world. Because ozone is not emitted into the atmosphere and all the ozone present at ground level has been formed there by atmospheric chemical reactions, these control actions have to act on the emissions of the ozone precursors: VOCs and NO_x. Actions to control VOC emissions have usually involved fitting three-way exhaust gas catalyst and evaporative canister systems to petrol-engined motor vehicles and by tackling emissions from oil refineries and the petrol distribution chain. Substitution of water-based paints, for example, has led to reductions in solvent emissions from homes. In this way, much progress has been achieved to reduce episodic peak ozone levels and hence exceedances of the environmental criteria set to protect human health, crops, and vegetation.

Synopsis

The three distinct processes of transport, stirring, and mixing are defined and described. The connection between relative dispersion in backward time and mixing is explained. Mixing in three-dimensional flows (e.g., boundary layer turbulence) and large-scale chaotic advection flows (e.g., in the free troposphere and stratosphere) is compared. A brief account is given of the processes which lead to mixing in the real atmosphere, particularly outside of the boundary layer, including how those processes have been constrained by chemical observations and modeling.

Introduction

The atmospheric flow has an important effect on the distribution of chemical species by moving them away from the location of their sources and toward the location of their sinks. This process is *transport*. Unless the flow is uniform in space, it also distorts the geometric structure of chemical concentration fields so as to bring air parcels with different chemical character into closer and closer proximity. This process may be called *stirring*. The stirring processes typically draw out a volume of air (perhaps air with an anomalous chemical concentration) into thin filaments or sheets. Ultimately, the distance between air parcels of differing chemical concentration is so small that molecular diffusion may act rapidly to homogenize the chemical concentration fields. This latter process is *mixing*. The three processes of transport, stirring, and mixing are depicted schematically in [Figure 1](#).

Without the stirring effect of the flow, timescales for diffusive homogenization would be extremely long. Consider the advection–diffusion equation for the concentration $\chi(\mathbf{x}, t)$ of some chemical species.

$$\frac{D\chi}{Dt} = \frac{\partial\chi}{\partial t} + \mathbf{u} \cdot \nabla\chi = \kappa \nabla^2 \chi \quad [1]$$

$$\text{Estimated size } \frac{\chi U}{L} \quad \frac{\kappa \chi}{L^2}$$

where $\mathbf{u}(\mathbf{x}, t)$ is the velocity field, with $\mathbf{x}$ a vector representing spatial position and t time, and κ is the molecular diffusivity. Suppose that a characteristic length scale for the concentration field and the velocity field is L and the characteristic velocity scale is U . These scales might, for example, be imposed by boundary conditions, geometry, or forcing. The corresponding estimates for the advection and diffusion terms (respectively the second term on the left-hand side and the term on the right-hand side) in [eqn \[1\]](#) are shown below the equation. Note first that the ratio of the advection term to the diffusion term is UL/κ , generally called the Peclet number (Pe). If this number is large then advection dominates diffusion. If it is small then diffusion dominates advection. It also follows from the above that the timescale for diffusion is given by L^2/κ .

In the atmosphere the molecular diffusivity of most gaseous chemical species varies from about $10^{-5} \text{ m}^2 \text{ s}^{-1}$ in the troposphere to $10^{-3} \text{ m}^2 \text{ s}^{-1}$ in the upper stratosphere to higher values still in the mesosphere and thermosphere. The corresponding estimate for the time needed for molecular diffusion to homogenize chemical concentrations in the troposphere and lower stratosphere over a distance of, say, 100 m would therefore be more than 10^8 s , i.e., a few years. In reality, the effect of molecular diffusion is considerably enhanced by the stirring effect of the flow, which reduces the length scale of the concentration field, thereby increasing the size of the diffusive term on the right-hand side of [eqn \[1\]](#),

Figure 1 Schematic showing three-stage process leading to mixing. Two air masses containing different chemicals are initially well separated. In stage A *transport* brings the two air masses into the same region. (One might more accurately call this *relative transport*.) However, length scales are still relatively large and diffusive timescales are long. In stage B, stirring distorts the chemical distributions into filaments or sheets, thereby reducing their characteristic length scales. As a result diffusive timescales are reduced and in stage C *mixing* between the air masses can occur, leading to homogenization (at the molecular scale) of chemical concentrations. Note that stages A and B have been separated here for clarity, but in many cases it may not be appropriate to distinguish between A and B.

which has magnitude $\kappa\chi/l^2$ when the length scale of the concentration field is l . The diffusive term therefore becomes comparable to the advective term when $\kappa/l^2 \sim U/L$, i.e., when $l \sim L(\kappa/UL)^{1/2} = LPe^{-1/2}$.

Stretching, Relative Dispersion, and Mixing

The stirring process involves the geometrical deformation of material lines and surfaces. One useful measure of the stirring effect of the flow is the rate at which material lines or surfaces are stretched. For example, the equation for a material line element $l(t)$ (where $l(t)$ represents the difference in position between two nearby marked fluid particles) is

$$\frac{dl}{dt} = l \cdot (\nabla \mathbf{u}) \quad [2]$$

This equation is valid providing that the separation distance $|l|$ is smaller than the length scale on which the flow varies. If there is a systematic tendency for nearby particles to separate then, for any pair of particles with finite initial separation, eqn [2] will eventually become invalid. Note that velocity gradient tensor on the right-hand side of this equation must be evaluated following one of the fluid particles defining the line element. It is therefore the time history of this tensor following the flow that determines the stretching. A very simple example is that where the flow is two dimensional and the velocity gradient tensor is steady, taking the form

$$(\nabla \mathbf{u})_{ij} = \left(\frac{\partial u_i}{\partial x_j} \right) = \begin{pmatrix} a & b-c \\ b+c & -a \end{pmatrix} \quad [3]$$

(chosen to match the requirement that the flow is incompressible, i.e., $\partial u_1/\partial x_1 + \partial u_2/\partial x_2 = 0$). Then it is straightforward to solve eqn [2] to show that if $a^2 + b^2 > c^2$ the solution is $l(t) = l_+ \mathbf{e}_+ \exp(\sqrt{a^2 + b^2 - c^2}t) + l_- \mathbf{e}_- \exp(-\sqrt{a^2 + b^2 - c^2}t)$, where l_+ and l_- are constants and $\mathbf{e}_+$ and $\mathbf{e}_-$ are constant vectors. The first term dominates at large time implying that the length of line elements increases exponentially with time and hence that there is effective relative dispersion of nearby fluid particles. On the other hand, if $a^2 + b^2 < c^2$, then the solutions of eqn [2] are oscillatory, i.e., there is no systematic increase with time.

The model above in which the velocity gradient tensor is constant in time is not very relevant to real atmospheric flows. (Note the model corresponds to the tensor being constant following an air parcel, not simply constant at fixed points in space.) In many realistic flows, particularly turbulent flows, the velocity gradient tensor experienced by an air parcel has a complex time variation and might be represented as a random function of time. A model where the velocity gradient tensor is represented as a random function, with certain specified statistical properties, is called a random-straining model. Such models predict that the exponential stretching is robust, although there is an important dependence of the rate of increase on the correlation time for the random variation of the velocity gradient tensor. More detailed investigation of more realistic models for a wide variety of atmospheric flows shows that there is very often exponential stretching of line elements at a rate that roughly corresponds to the size of the components of the velocity gradient tensor. Exceptions might be in interior of long-lived eddies, where the regime for oscillatory solutions of eqn [2] might be relevant, and in cases where the correlation time for the velocity gradient tensor is very short, when the stretching rate will be reduced.

To emphasize the implications of material line lengthening and relative dispersion for stirring and mixing, it is useful to consider the evolution of a small material surface (assumed smaller than the length scale on which the velocity field varies) that is initially a sphere (or, in two dimensions, a small material contour that is initially a circle). The tendency of line elements to stretch, as described by eqn [2], implies that the sphere is deformed into an ellipsoid, at least one axis of which systematically increases in time. In an incompressible flow, the volume of the sphere remains constant with time, therefore the systematic increase in length of one axis is inevitably accompanied by the systematic decrease in length of another axis. This is a manifestation of the scale reduction that leads to mixing. In a compressible flow, there is no absolute constraint on the volume of the sphere, but nonetheless it is the case that in almost all flows the density will not systematically reduce, implying again that one axis must systematically reduce in length. The geometry of the ellipsoidal material surface becomes more complicated when its maximum dimension becomes as large as the length scale on which the velocity field varies. The surface is then strongly distorted and folded as different parts of the surface sample very different velocity gradients.

The relevance of deformation of material surfaces or curves to the evolution of the concentration of a chemical species is emphasized by noting that a similar picture holds in backward time (see Figure 2). Neglecting the effects of diffusivity for the present, the values of concentration in a small spherical region will be the values that were present in the same material region

Figure 2 Schematic of the deformation of two material curves/surfaces. The top panel shows a small circle at time $t = 0$, which is then deformed into an ellipse (while its maximum dimension is less than the characteristic scale of the flow) and then into a more complex structure (as different parts of the curve experience very different velocity fields). The bottom panel shows a small circle at time $t = T$, which originated from a complex filamental structure at $t = 0$. This structure may be obtained by deforming the circle in backward time. The values of chemical concentration inside the circle at $t = T$ are just those sampled by the filamental structure at time $t = 0$. (Note that the two panels do not imply any kind of reversibility – the lower panel corresponds to a particular choice of initial condition that involves into a circle at time T . If the evolution was continued after time T the circle would stretch and eventually become geometrically complex, much as in the top panel.)

at the initial time. If that material region is stretched (in backward time) to length scales greater than those on which the concentration varies in the initial condition, then the small spherical region will contain a wide range of different concentration values, and it can be safely assumed that the effect of diffusivity will eventually be to homogenize those values over the region. The intimate relation between relative dispersion, i.e., the separation of nearby particles, and mixing has been exploited in many theoretical studies of the mixing problem.

The stirring and mixing process has so far been described as completely generic. One could equally well be considering the mixing of a smoke plume from a factory into the surrounding boundary layer air, or the mixing into the upper troposphere of boundary layer air that has been lofted in a convective cloud or a convective complex, or the mixing of stratospheric ozone-depleted Antarctic air into midlatitudes as the polar vortex breaks up in the late spring. These examples range in scales from a hundred meters or so to several thousand kilometers. But the flows that are responsible for stirring and mixing in each of the cases are very different and that has important implications for the stirring and mixing process.

Mixing in Three-Dimensional Turbulence

One important category of flow that gives rise to effective mixing is three-dimensional turbulence that occurs, for example, in the boundary layer and in convective clouds and

also in intermittent internal mixing events in the troposphere and the stratosphere. The dynamics of three-dimensional turbulence is characterized by energy input at some large scale, L . If velocities at the large scale are of typical size U , then the energy input rate ε satisfies $\varepsilon \sim U^3/L$. The dynamics of the turbulent eddies transfer energy from the input scale to smaller and smaller scales through a so-called inertial range. The classical Kolmogorov scaling predicts that in the inertial range the velocity fluctuations at length scale l vary as $\varepsilon^{1/3} l^{1/3} = U(l/L)^{1/3}$ and therefore that the typical size of components of the velocity gradient tensor is $(U/L)(L/l)^{2/3}$. The energy transfer is terminated at the dissipation scale l_ν , often called the *Kolmogorov scale*, where molecular diffusion of momentum becomes competitive with other flow processes. l_ν may be estimated by assuming that stretching and diffusion timescales are equal, implying that $l_\nu \sim \nu^{3/4} \varepsilon^{-1/4}$, where ν is the momentum diffusivity. The rate of energy dissipation at the Kolmogorov scale must, in a steady state, equal ε , the rate of energy input at the large scale.

It follows that the largest contributions to the stretching come from the velocity field at the dissipation scale and furthermore the stretching rate at those scales is considerably larger (by a factor of $(UL/\nu)^{1/2}$) than that estimated using velocity and length scales at the energy input scale. (Note the velocity gradient is a good estimate for the inverse of the timescale for line stretching since, for three-dimensional turbulence, the time series of velocity gradient experienced by an air parcel is essentially random and, furthermore, the correlation time is of order the inverse of the velocity gradient at the dissipation scale.)

If the diffusivity κ for the chemical species is much less than ν , then the Peclet number at the Kolmogorov scale may be large and the eddies at this scale must stir the chemical concentration field to a smaller scale (often called the *Batchelor scale*) for diffusive homogenization to occur. However, for most chemical species of interest in the atmosphere we may assume $\kappa \sim \nu$ and therefore diffusive homogenization occurs at the Kolmogorov scale. The timescale required for a chemical concentration field that is initially on the energy input scale, i.e., large scale, to be geometrically deformed until molecular diffusion is important may be estimated by assuming that $(L/U)(l/L)^{2/3}$ is roughly the time required to reduce the scale from l to $l/2$. Summing the times needed to reduce the scale from L to l_ν gives a convergent geometric series whose sum is estimated by L/U multiplied by some moderate factor that is independent of ν and hence κ , if these are small. The timescale required for homogenization on the molecular scale is therefore the same order of magnitude as the time required for advection around the turbulent region on the large scale. Thus, the timescale for mixing within a region containing three-dimensional turbulent flow is the same order of magnitude as the timescale for transport across that region. The implication is that three-dimensional turbulence is very effective at mixing and that, to some reasonable approximation, if there is time for transport of air parcels across a turbulent region then there is also time for mixing within that region.

The fact that stretching is dominated by velocity fluctuations at the Kolmogorov scale implies that the geometrical structure of the chemical concentration field also varies on this scale. An example of a typical chemical concentration field is shown in **Figure 3** (top panel). (This field has been obtained by

Figure 3 (a) Chemical concentration field resulting from numerical solution of the advection-diffusion equation for a two-dimensional flow in which there is small-scale energy input. This gives rise to an energy spectrum similar to that predicted by Kolmogorov scaling for three-dimensional turbulence and many aspects of the chemical concentration field shown here, particularly the small-scale geometry, are as they would be in three-dimensional turbulence. (The energy transfer in the two-dimensional case is upscale rather than downscale, but this by itself is not particularly important for the chemical concentration field.) (b) Chemical concentration field resulting from numerical solution of the advection-diffusion equation for specified large-scale flow in which the velocity is a smoothly but randomly varying function of time.

numerical solution of the advection-diffusion equation in a model flow, not a three-dimensional turbulent flow but an artificially forced two-dimensional flow that also exhibits Kolmogorov scaling.) The orientation of the contours of concentration changes on the scale of the smallest eddies in the flow.

Mixing in three-dimensional turbulent flows has been much studied in the laboratory and is of great practical significance because of its relation to the dispersion of pollutants in the atmospheric boundary layer. Research has focused on considering the mixing problem via the problem of relative dispersion, and stochastic models have carefully been formulated and refined to describe this relative dispersion process.

Large-Scale Flows: Quasi-Two-Dimensional Turbulence and Chaotic Advection

Rotation and buoyancy stratification both tend to inhibit three-dimensional turbulence on sufficiently large scales. On scales larger than a few tens of kilometers transport is accomplished by frontal systems, cyclones, and anticyclones and, in the stratosphere, propagating and breaking planetary-scale Rossby waves. The stable stratification and geometric constraints ensure that air parcel trajectories are along weakly sloping surfaces, so that horizontal displacements are generally much larger than vertical displacements.

These flows have a dual character, with some aspects of their behavior appearing organized and wavelike and other aspects exhibiting considerable nonlinearity and randomness. In the latter respect, these flows might therefore be regarded as a kind of turbulence, analogous to the two-dimensional turbulence studied in idealized numerical simulations and laboratory experiments. However, the strong difference of these flows from three-dimensional turbulence is that strong vortex stretching is inhibited and therefore the cascade of energy to small scales is inhibited. The velocity field essentially has a finite spatial scale and hence there is no strong increase of velocity gradients as scale shrinks.

It is now realized that flows such as these, with a relatively simple structure in space and time, may be highly effective at stirring and mixing through a phenomenon known as ‘chaotic advection.’ The idea here is that velocity fields with a very simple structure in space and time may lead to complex and irregular, i.e., chaotic, particle trajectories with, for example, the distance between initially nearby particles increasing exponentially in time. As explained above, this separation of nearby particles implies that chemical concentration fields rapidly become complex, with variations on scales much smaller than that of the advecting flow.

In large-scale chaotic advection type flows the magnitude of velocity gradients is constant with scale and may be estimated as L/U , where L is a typical length scale and U is a typical velocity magnitude of the large-scale flow. In this case, diffusive mixing takes place on a length scale of $(\kappa L/U)^{1/2}$. The time to reach this scale from the large scale is $(L/U) \log (UL/\kappa)^{1/2}$, i.e., considerably larger than the timescale for transport by the large-scale flow. The implication is that in these flows advected chemical species may be spread across the flow domain on the large scale, but for a substantial time may remain unmixed on the small scale (in contrast to the case in three-dimensional turbulence). Furthermore, the fact that the velocity field itself varies only weakly on the scale $(\kappa L/U)^{1/2}$ suggests that the chemical concentration fields tend to be aligned in smooth (but thin) filaments or sheets. Such filaments or sheets of anomalous chemical species, that have not yet been mixed with

their environment, are widely observed in the atmosphere. An example of chemical concentration fields arising in a two-dimensional chaotic advection flow is shown in [Figure 3](#) (bottom panel). (Contrast with the top panel of [Figure 3](#).)

Mixing Processes in the Real Atmosphere

In the real atmosphere three-dimensional turbulence is inevitably affected by the presence of stable density stratification, which implies that energy input is needed to move fluid particles in the vertical. Broadly speaking, the effect of the stratification is to limit the vertical length scales of the turbulence and hence the vertical length scales over which mixing can occur. The dynamics of the mixing also tends to lead to the formation of interfaces at the upper or lower limits of the turbulent regions across which there are strong density gradients. The stability of these interfaces implies that mixing across them occurs relatively infrequently, often through complex phenomena such as the breaking of waves propagating on the interfaces themselves.

For the planetary boundary layer, the role of stable stratification is to limit the height of the turbulent layer. The strong stable stratification often found at the top of the boundary layer has an important effect on exchange between the turbulent boundary layer and the free atmosphere above it. But when considering transport within the boundary layer itself stratification may often be neglected.

In the 'free' atmosphere above the boundary layer, there is certainly no permanent 'background' field of three-dimensional turbulence. In the troposphere convection gives rise to turbulence, but the fraction of the atmosphere that is actively convecting at any instant is relatively small. In the upper troposphere and stratosphere, there is little or no convection, but localized regions of turbulence arise through shear instability or through breaking of inertia-gravity waves. These turbulent regions form sporadically, mix in a localized region, and then decay. Thus, outside the planetary boundary layer, turbulent mixing occurs through the net effect of localized, intermittent turbulent events.

Evidence of the effect of turbulence mixing in the free troposphere and stratosphere comes, for example, for combined observational and modeling studies of layered structures in chemical species, such as ozone, water vapor, and carbon monoxide. Layered structures, with vertical scales of a few hundred meters, have commonly been observed in the troposphere, for example, from *in situ* observations from aircraft. The fact that these structures have survived for several days, deduced from the distance between the observation and the likely region of origin, implies that turbulent mixing cannot be too strong. On the other hand, careful comparison between observations (sometime multiple observations of the same air mass as it is transported over several days) and predictions from Lagrangian models (where air parcels are transported by

the wind fields defined by meteorological analysis data sets) shows that some mixing certainly takes place, typically corresponding to a vertical diffusivity of $1 \text{ m}^2 \text{ s}^{-1}$ in the troposphere and $0.1 \text{ m}^2 \text{ s}^{-1}$ in the lower stratosphere.

The route by which air masses with different chemical characteristics are mixed in the free atmosphere can be summarized as follows. Long-range transport and stirring on the large scale is accomplished by quasi-horizontal motion that draws chemical fields out into thin sloping sheets (which appear as thin filaments on a quasi-horizontal surface). If there was no three-dimensional turbulence, then mixing would eventually be achieved by molecular diffusion alone, but this mixing would occur at very small scales. In practice the effects of molecular diffusion are enhanced, probably through intermittent encounters of air parcels with three-dimensional turbulence. This enhancement appears to be substantial in the troposphere, where convection and other mechanisms for generation of active three-dimensional turbulence are common, weaker in the lower stratosphere, and then to increase again in the upper stratosphere and mesosphere, where three-dimensional turbulence associated with the breaking of gravity waves is more widespread.

Introduction

Historical interest in two-dimensional (2D) turbulence in the atmospheric and oceanic sciences stems from the fact that the equation describing the conservation of potential vorticity in a thin layer of fluid on a rotating sphere (based on the shallow-water equations) reduces to the much simpler equations for a 2D incompressible fluid (the Navier–Stokes equations) when the characteristic horizontal length scale, L , is small enough such that the flow does not feel the effect of the Earth's sphericity and yet large enough such that the quasi-geostrophic approximation is valid. In this case, the governing equations reduce to

$$\frac{\partial \zeta}{\partial t} + \mathbf{u} \cdot \nabla \zeta = \nu \nabla^2 \zeta + F, \quad \nabla \cdot \mathbf{u} = 0 \quad [1]$$

where $\zeta = \hat{\mathbf{k}} \cdot \nabla \times \mathbf{u}$ is the vertical vorticity, $\mathbf{u}$ is the velocity, $\hat{\mathbf{k}}$ is the unit vector normal to the flow plane, and F represents an unspecified vorticity forcing. In the limit where the Reynolds number, $Re = UL/\nu$ (U is a characteristic velocity), is large, the behavior is often highly nonlinear and turbulent. Although the range of length scales over which this is a good approximation to geophysical fluid flow is at most a factor of 10–100, eqn [1] has been used as a simple conceptual model. This is partially justified by the fact that, even though large-scale atmospheric flow is not exactly 2D, this is the simplest setting in which to explore the nature of large nonlinearity. In addition, the strong stratification in the atmosphere inhibits vertical velocity, yielding approximately layerwise 2D flow. Since analytical techniques are lacking, laboratory experimentation and numerical simulation have provided a large part of our understanding today. Clearly, a much wider range of active length scales can be simulated in 2D than in 3D.

Cascade Phenomenologies

Theoretical approaches to turbulence have traditionally been based on the fact that, no matter how nonlinearly complicated the flow is, in the absence of forcing and molecular viscosity, it must conserve its full set of invariants, such as energy. 2D turbulence is distinguished from its 3D counterpart by the lack of vortex tube stretching, implying that the vorticity is conserved by each fluid parcel. A distinguished role in 2D turbulence theory is played by the mean-square vorticity or enstrophy, $Z = \frac{1}{2} \langle \zeta^2 \rangle$, where angle brackets are averages over a statistical ensemble of such flows. Simultaneous conservation of enstrophy and energy, $E = \frac{1}{2} \langle \mathbf{u} \cdot \mathbf{u} \rangle$, yield turbulent behavior in 2D fluids which is quite different from that in 3D. This is best illustrated by expressing the fields in terms of their Fourier coefficients. If we consider flow in a doubly periodic domain of length L and then take the limit $L \rightarrow \infty$, we can describe turbulence that is statistically homogeneous,

meaning that statistics do not depend on the position at which they are measured. In such a domain, a field ζ can be expressed as

$$\zeta(\mathbf{r}, t) = \sum_{\mathbf{k}} \hat{\zeta}_{\mathbf{k}}(t) e^{i\mathbf{k} \cdot \mathbf{r}} \quad [2]$$

where $\mathbf{r} = (x, y)$ is the position vector and $\mathbf{k} = (k_x, k_y)$ is the wave vector. The enstrophy is

$$Z = \frac{1}{2} \sum_{\mathbf{k}} \langle \hat{\zeta}_{\mathbf{k}}(t) \hat{\zeta}_{\mathbf{k}}^*(t) \rangle \quad [3]$$

where $*$ denotes complex conjugation. After taking the limit $L \rightarrow \infty$, the sums can be expressed as integrals. The 2D wave vector integration can be performed using polar coordinates $k = (k_x^2 + k_y^2)^{1/2}$ and $\theta_k = \tan^{-1} k_y/k_x$. Since eqn [1] is statistically isotropic, the integration in θ_k simply gives $2\pi k$, yielding the enstrophy as

$$Z = \int Z(k) dk \quad [4]$$

where the enstrophy spectrum is $Z(k) = \pi k \langle \hat{\zeta}_{\mathbf{k}} \hat{\zeta}_{\mathbf{k}}^* \rangle$. The same operations on the velocity field yield

$$E = \int E(k) dk \quad [5]$$

where the energy spectrum is $E(k) = \pi k \langle \hat{\mathbf{u}}_{\mathbf{k}} \cdot \hat{\mathbf{u}}_{\mathbf{k}}^* \rangle$ and, owing to the relationship between vorticity and velocity, $Z(k) = k^2 E(k)$.

Consider a set of initial conditions characterized by a thin energy spectrum localized near some intermediate wavenumber k_i . If the initial spectral distribution is thin enough, we can quantify k_i by using the first moment of $E(k)$, i.e.,

$$k_i = \frac{\int k E(k) dk}{\int E(k) dk} \quad [6]$$

How will the energy spectrum evolve in time? One of the fundamental characteristics of turbulence is that it mixes the fluid. A very thin energy spectrum, implying that only a narrow range of scales is excited, is a rather ordered low-entropy state. As the nonlinear term spreads the energy around from mode to mode in the complex vortex interactions discussed below, we expect that the width, W , of the energy spectrum will increase. Defining W via

$$W^2 = \frac{\int (k - k_i)^2 E(k) dk}{\int E(k) dk} \quad [7]$$

we require that $dW^2/dt > 0$, implying

$$\frac{dW^2}{dt} = -\frac{dk_i^2}{dt} > 0 \quad [8]$$

taking into account the invariance of the energy and enstrophy along with the definition of k_i . If the width of the initial energy spectrum increases, then the characteristic wavenumber, k_i , must decrease. In other words, the typical length scale of the eddy motions must increase with time. This is in marked

contrast to 3D turbulence where the transfer is to eddies of ever-diminishing size.

At the same time as energy is transferred to larger scales, the enstrophy is transferred to smaller scales. This can be illustrated by the fact that each fluid parcel conserves its vorticity, implying that as turbulence mixes the fluid, vorticity contours are stretched out into ever-longer curves (see Figure 2). This has the consequence of reducing mean distances between contours, thereby increasing gradients. The variance of vorticity gradients can be expressed as $\int k^2 Z(k) dk$. If the enstrophy ($\int Z(k) dk$) is constant, but vorticity gradients increase, vorticity must be transferred to larger wavenumbers or smaller scales.

The notion that energy is transferred to larger scales while enstrophy is transferred to smaller scales in 2D turbulence led to the formulation of cascade phenomenologies analogous to that of Kolmogorov for 3D flow. A major difference between the 3D and 2D phenomenologies is that an *a posteriori* analysis shows the 2D result to be inconsistent with one of the hypotheses. This will be discussed further below. Assume that energy is injected by external forcing at a rate ε and also that this forcing is active only over a narrow range of wavenumbers centered on k_f . The forcing also injects enstrophy at a rate $\eta \sim k_f^2 \varepsilon$. We also assume that there is a long 'inertial' range of wavenumbers where neither the forcing nor the dissipation are important. This can only be true if the nonlinear transfer is local in k . In other words, it must proceed via numerous small jumps in wavenumber. In each step of the process some information on the nature of the forcing is lost, such that eventually at intermediate wavenumbers the result is independent of the forcing. In order to achieve statistical stationarity, the enstrophy injection at k_f at rate η must be balanced by its dissipation at small scales at the same rate. It therefore follows that there is a constant downscale flux η of enstrophy across the entire inertial range. Dimensional analysis then yields the energy spectrum

$$\eta = \text{const} \sim \frac{\text{enstrophy}(k)}{\text{time}(k)} \sim \frac{k^3 E(k)}{[k^3 E(k)]^{-1/2}} \quad [9]$$

where the quantity $\text{time}(k)$ refers to the time scale of enstrophy transfer at k . Here it was assumed that the enstrophy near

Figure 1 Energy spectrum of 2D turbulence at statistical stationarity showing the direct enstrophy cascade and the inverse energy cascade.

wavenumber k is $kZ(k)$ and that $\text{time}(k) \sim L(k)/U(k) \sim [k^3 E(k)]^{-1/2}$, since $U(k) \sim [kE(k)]^{1/2}$ and $L(k) \sim k^{-1}$. These relations assume the transfer to be local, i.e., the transfer into k comes from other modes near k , such that all quantities are evaluated locally. Solving for $E(k)$ gives

$$E(k) \sim \eta^{2/3} k^{-3} \quad [10]$$

for the energy spectrum in the downscale (or direct) enstrophy cascade range. As mentioned above, an *a posteriori* analysis of this theoretical spectrum reveals the nonlinear transfer in the inertial range to be nonlocal. In other words, instead of the enstrophy transfer proceeding by numerous small jumps in length scale, as required if the intermediate scales' dynamics are independent of F , the transfer takes rather larger jumps. In the upscale energy cascade range, the reasoning is as for Kolmogorov and

$$E(k) \sim \varepsilon^{2/3} k^{-5/3} \quad [11]$$

Strictly speaking, a mechanism is required to dissipate energy at scales much larger than the forcing scale in order for eqn [11] to reach the statistical stationarity assumed here. One physical possibility is the scale-independent dissipation inherent in the Ekman layer, provided that it is negligible over the inertial range. Both cascade ranges are shown schematically in Figure 1.

Numerical Simulations

As stated above, 2D turbulence is less computationally intensive than its 3D counterpart. In the early 1970s, numerical simulations began to be possible at low Re . They showed energy spectra consistently steeper than the k^{-3} prediction in the enstrophy cascade. By 1981, it was clear that a major surprise of these simulations was the development of intermittency in the vorticity field. Typically decaying (i.e., $F = 0$) turbulence was simulated starting from a random initial field with Gaussian statistics. Theory also predicts the energy spectrum [10] for the decay case. The numerical results showed that like-signed extrema had a tendency to merge and form larger vortices. In addition, close approaches of vortices stretched out long vorticity filaments whose width decreased until the dissipation scale was reached. The net result of these complicated vortex interactions is the growth of relatively large quiescent regions between a diminishing number of intense vortices. A typical snapshot of a simulation vorticity field is displayed in Figure 2. During the 1980s and 1990s, resolutions continued to increase and it became clear that the spectra were steeper than the k^{-3} prediction and that if (by some numerical trick such as scrambling the complex phases of the $\hat{\zeta}_k$) the intermittency was reduced, the evolution was more consistent with the k^{-3} phenomenology.

It must be stated that any inertial range argument assumes a sufficiently large range of wavenumbers such that forcing and dissipation are negligible. Unfortunately, it is not entirely clear how large this range must be for the approximation to be valid. It may be that resolutions much larger than those currently used (4096^2) are required. If this is the case, the relevance to atmospheric and oceanic dynamics is not obvious. It may also

Figure 2 Vorticity field in a high-resolution simulation of decaying 2D turbulence from random initial conditions.

be that the nonlocalness of enstrophy transfer is responsible for the failure of eqn [10], although a theoretical attempt to account for this yields a spectrum (with a logarithmic correction factor) not much different from eqn [10], whereas the simulation spectra are considerably steeper.

In addition to simulations of decaying turbulence, high-resolution simulations of forced turbulence have been performed. They also tend to show spectra steeper than k^{-3} in the enstrophy cascade range as well as a dependence on the nature of the forcing mechanism throughout the resolved range, indicating that we have not yet achieved the resolutions required for universal (forcing-independent) behavior. Simulations of the enstrophy cascade are performed by forcing at a low wavenumber, whereas simulations of the inverse energy cascade result when k_f is larger. The latter have generally shown reasonable agreement with eqn [11], although this is not the case in all studies.

Vortex Dynamics

Current numerical and theoretical research on this subject focuses almost entirely on the vortices and their dynamics. The cascade phenomenologies discussed above are crude examples of statistical theories where the flow variables are assumed to be independent random oscillators weakly coupled by their contribution to the global invariants. More sophisticated theories based on this idea also fail in the presence of intermittent vortices. The reason is presumably that the Fourier transform of a thin isolated peak in x covers a wide range in k . As a result, the Fourier modes are not weakly coupled but rather describe long-lived structures moving around in space. This has caused some to advocate abandoning the traditional Fourier approach.

The intermittency of the vorticity in simulations of decaying 2D turbulence suggests that a model based on a collection of point vortices might be a good approximation. A vortex which

persists much longer than the time it takes a fluid parcel to circle around its center must be an essentially nondissipative structure. As a result, a Hamiltonian formulation has been employed and compared favorably with full simulations of eqn [1]. Ballistics theory, in which the vortices behave much like billiard balls, has also been applied. Unfortunately, these theories are not a natural setting to describe the observed mergers of like-signed vortices which lead to the growth of the characteristic length scale. Merger rules must be formulated and inserted into the theories by appealing to comparison with experiment or numerical simulation. The extent to which these empirically derived rules are independent of such details as the initial conditions is currently a matter of debate.

Since merger rules form an intrinsic part of discrete vortex theories, recent attention has been directed at the vortex interactions themselves. It has long been observed that the most intense vortices at the end of a long simulation can be traced all the way back to the initial conditions, where they were undistinguished extrema in a field with Gaussian statistics. Since the viscous term in eqn [1] can only diffuse vorticity down vorticity gradients, and since the other terms ensure conservation of vorticity by each fluid parcel, the central vorticity in a vortex can only decrease with time. The most intense vortices in the later stages are therefore those having decayed the least and those having sustained the least damage in their interactions with other vortices. A closer look at these interactions shows that, while some vortices do not survive, those that do are rendered steeper by the interactions. That is to say, the vorticity becomes more uniform in the center while the vorticity gradient is increased at the edges. This process has been called vortex erosion or stripping and it leads to a rather robust central value of vorticity which changes little with time.

Perhaps the first step in formulating vortex merger rules is to determine the statistics of the decay of ρ , the total number of vortices per unit area in decaying 2D turbulence. Numerical evaluations of this quantity differ from simulation to simulation as a function of the Reynolds number and the initial conditions. An interesting idea proposed to analyze a simulation with a narrow range of vortex amplitudes, ζ_{ext} , and radii, a . The total energy can be estimated dimensionally as

$$E \sim \rho a^4 \zeta_{\text{ext}}^2 \quad [12]$$

and the enstrophy is

$$Z \sim \rho a^2 \zeta_{\text{ext}}^2 \quad [13]$$

Since energy is transferred to larger scales and is therefore not dissipated significantly, E is held fixed. Based on the observed tendencies for the most intense vortices' central vorticities to be robust to interactions, ζ_{ext} is held constant too. Assuming ρ to decay as a power of time, $\rho \sim t^{-\xi}$, the other statistics follow as $a \sim t^{\xi/4}$ and $Z \sim t^{-\xi/2}$. The simulation discussed here gave $\xi \approx 0.75$. While these temporal scaling relations are based on the measured value of $\rho(t)$, they also provided good estimates of the simulation $a(t)$ and $Z(t)$. How well they apply when vortex properties are not narrowly distributed is still a matter of debate.

Vortex theories take no account of the low-amplitude vorticity filaments which can always be observed between the intense coherent structures. This background 'sea' of vorticity clearly interacts with the vortices in that they emerge from it at

Figure 3 Schematic of the scaled vorticity probability density function. The dashed line represents the universal function, f (see text), while the solid lines denote the probability at several times such that the hyperbolic range widens with time.

small times. Their close interactions have also been observed to stretch out weak filaments which then decay into the background sea. It remains to be seen how dynamically important the sea is to the evolution of the turbulence. A schematic of the vorticity's probability density function for decaying 2D turbulence is shown in Figure 3. If the probability of finding a vorticity between ζ and $\zeta + d\zeta$ is denoted as $p(\zeta)d\zeta$, then a self-similar behavior has been observed in decaying 2D turbulence such that

$$p(\zeta) \sim t f(\zeta t) \quad [14]$$

except at large $|\zeta|t$, where the curve drops quickly to zero owing to the fact that the largest vorticities in the field are relatively constant in time. In eqn [14] f is a universal dimensionless function. Figure 3 shows that for low vorticities ($|\zeta|t < x^* \approx$) the probability density drops off rapidly with increasing ζ . The weak background sea of vorticity filaments is described by this range. When $x^* < |\zeta|t < x_m$ the probability density decays as

$$p(\zeta) \sim \frac{t}{(|\zeta|t)^{1.4}} \quad [15]$$

This is referred to as a hyperbolic distribution and it describes fields which are very intermittent indeed, corresponding to the isolated coherent vortices. At $|\zeta|t > x_m(t)$ the probability drops rapidly to zero. If extreme vorticities are conserved as in the simple scaling above, then $x_m(t) \sim t$ and the probability

density provides a more standard statistical definition of the quantity ζ_{ext} . How $x_m(t)$ behaves with time and as a function of the Reynolds number needs further investigation and is essentially a function of the vortex dynamics. The self-similar decay of vorticity shows an increasingly wide hyperbolic vortex range and a diminishing background sea as time proceeds.

Conclusions

Over the last 30 years numerical simulations of 2D turbulence have surprised researchers a great deal. The failure of the classical cascade phenomenologies and its attribution to the development of isolated coherent vortices has been the subject of much attention in the scientific literature. Clearly, a lot has been learned from the study of this simplest of models of a highly nonlinear turbulent fluid.

It was stated in the introduction that one of the reasons 2D turbulence has sparked such interest in the scientific community is that it was possible to test out at least some of the ideas numerically on even the relatively primitive computers of the early 1970s. Since then, the history of the subject parallels that of computational science. In spite of the fact that current computers allow scientists to move on to more realistic atmospheric and oceanic flows, many of the surprising elements of early simulations of 2D turbulence are still unexplained. The development of isolated vortices in the decay case is still somewhat mysterious and there exists no theory to describe their interactions once they have developed. There is still a lot more work to be done.

T_{Lw} Lagrangian timescale for crosswind velocity.

T_{Lw} Lagrangian timescale for vertical velocity.

t Travel time from source to receptor.

$\tilde{U}$ Instantaneous wind speed.

U Average wind speed.

u Wind speed fluctuation defined as $\tilde{U} - U$.

u_* Surface friction velocity.

w_s Gravitational settling velocity of a heavy particle.

δ Deviation of time-averaged mean about the ensemble mean.

ϵ Rate of dissipation of turbulent kinetic energy.

ρ Density of air.

σ_c Standard deviation of concentration fluctuations.

σ_v Standard deviation of crosswind velocity component.

σ_w Standard deviation of vertical velocity component.

σ_y Lateral dimension (or spread) for Gaussian plume model.

σ_z Vertical dimension (or spread) for Gaussian plume model.

τ Surface shear stress.

τ_{Leff} Effective Lagrangian timescale of a heavy particle.

τ_{particle} Relaxation timescale of a heavy particle.

Introduction

Turbulent diffusion or, more correctly, turbulent dispersion addresses the problem of estimating the concentration field in a turbulent flow. Our ignorance of the details of the turbulent velocity field translates into uncertainty in estimating the details of the concentration field. Thus, as in other problems related to turbulence, the goal of turbulent dispersion is limited to understanding the ensemble-averaged statistics of the concentration field and the associated fluxes that govern the field.

Most of our understanding of turbulent dispersion is couched in terms of semiempirical models that have been developed by fitting tentative theories to observations. For example, models for dispersion in the surface boundary layer are based on tracer experiments conducted in Prairie Grass, Nebraska, USA, in the 1950s. The development of models for dispersion in the convective boundary layer (CBL) has been guided by laboratory experiments conducted by Willis and Deardorff in the 1970s. Thus, to a large extent, our understanding of turbulent dispersion consists of a patchwork of semiempirical models, each of which describes a limited set of observations. The primary goal of this

article is to provide the reader an understanding of these semi-empirical models. It is only over the past 10 years that attempts have been made to develop methods that can be applied to a large class of problems. These methods will be discussed in the last part of this article.

This article assumes that the reader is familiar with the fundamentals of turbulence in the atmospheric boundary layer. To keep this article to a manageable size, we will not deal with several important topics including the effects of turbulence on chemical reactions. We begin with the statement of the problem that the techniques of turbulent dispersion attempt to solve.

The Problem of Turbulent Dispersion

The evolution of the concentration field of a species is governed by the mass conservation equation, eqn [1], where the 'squiggle' overbar refers to the instantaneous field, and D is the molecular diffusivity of the chemical species in the fluid.

$$\frac{\partial \tilde{C}}{\partial t} + \frac{\partial}{\partial x_i} (\tilde{U}_i \tilde{C}) = D \frac{\partial^2 \tilde{C}}{\partial x_i \partial x_i} \quad [1]$$

Because the instantaneous velocity field is unknown, we have to limit ourselves to estimating the ensemble-averaged mean and the associated statistics of the concentration field.

To define an ensemble, we express the instantaneous velocity field as the sum of a known velocity field, U_i , and the unknown deviation, u_i , as in eqn [2].

$$\tilde{U}_i = U_i + u_i \quad [2]$$

Then, an ensemble is defined as the infinite set of possible concentrations corresponding to a given U_i . Note that the definition of an ensemble is arbitrary because it depends on what we know about the velocity field. Each member of this ensemble corresponds to the component of the unknown velocity field, u_i ; we assume that we know something about the statistics of this unknown field. The concentration associated with each member of the ensemble can be written as eqn [3], where C is the average obtained over all possible concentration fields in the ensemble.

$$\tilde{C} = C + c \quad [3]$$

Substituting eqn [3] into eqn [1] and averaging over the ensemble yield eqn [4], where the overbar refers to the ensemble average, the subscripted index refers to coordinate direction, and repeated indices imply summation. This equation can be solved only by modeling the turbulent flux term, $\overline{u_i c}$, using known properties of the velocity field. Before we take up models for this term, let us consider the problem in turbulent dispersion that has to a large extent motivated the development of the field.

$$\frac{\partial C}{\partial t} + \frac{\partial}{\partial x_i} (U_i C + \overline{u_i c}) = D \frac{\partial^2 C}{\partial x_i \partial x_i} \quad [4]$$

The Point Source in the Atmospheric Boundary Layer

The classical problem of turbulent dispersion in the atmospheric boundary is that of a continuous source emitting material at some height above the ground (see Figure 1). If the

ground is taken to be the reference height, with the x -axis of the coordinate system aligned along the wind direction at the source, empirical evidence indicates that the time-averaged (typically 1 h) concentration field can be described in terms of the Gaussian distribution by eqn [5], where y is the cross-wind coordinate, Q is the source strength (mass/time), h_s is the height of the source above ground, U is the time-averaged wind speed at source height, and σ_y and σ_z are the plume spreads corresponding to the Gaussian distribution.

$$C(x, y, z) = \frac{Q}{2\pi\sigma_y\sigma_z U} \exp \left[-\frac{(z - h_s)^2}{2\sigma_z^2} - \frac{y^2}{2\sigma_y^2} \right] \quad [5]$$

The effect of the ground on concentrations is accounted for by making sure that there is no flux of material through the plane at $z = 0$. The mathematical trick to achieve this is to place an 'image' source at a distance $z = -h_s$; the upward flux from this image source essentially cancels out the downward flux from the real source. Then, the concentration can be described by eqn [6].

$$C(x, y, z) = \frac{Q}{2\pi\sigma_y\sigma_z U} \exp \left[-\frac{y^2}{2\sigma_y^2} \right] \times \left\{ \exp \left[-\frac{(z - h_s)^2}{2\sigma_z^2} \right] + \exp \left[-\frac{(z + h_s)^2}{2\sigma_z^2} \right] \right\} \quad [6]$$

In the real atmosphere, dispersion in the upward direction is limited by the height of the atmospheric boundary layer. This limitation of vertical mixing is incorporated into the Gaussian formulation by reflecting off the top of the mixed layer. When the material is 'reflected' from both the ground as well as the top of the mixed layer, it is necessary to account for the infinite set of 'reflections' from the two surfaces. This can be readily accounted for in the Gaussian formulation.

The point source solution is the kernel for the integral that is used to estimate dispersion from a variety of sources, including line and volume sources. Most dispersion models that apply to spatial scales of tens of kilometers are based on eqns [5] and [6]. The plume spreads or σ values are empirically derived from observations. It turns out that we continue to use plume-spread formulations first recommended by Pasquill in the 1960s. These formulations, largely based on the Prairie Grass experiment, relate plume spread to surface meteorological measurements such as wind speed and cloud cover. The advances in micrometeorology during the 1970s provided the incentive to develop dispersion models that relied on theoretical understanding of dispersion.

The preceding expression for the concentration field is essentially an empirical description of observations. Equation [5] is a formal solution to the point source problem only when the turbulence field is homogeneous, and the velocity distribution is Gaussian. Under these circumstances, the concentration field can be analyzed using a statistical approach, first proposed by Taylor.

Statistical Analysis of Dispersion

Consider a source located at ' s ' emitting particles continuously into a turbulent flow. If the mean flow and turbulence are

Figure 1 Turbulent dispersion from a point source.

steady, the ensemble-averaged concentration at ' r ,' $C(\mathbf{r})$ can be shown to be

$$C(\mathbf{r}) = Q \int_0^{\infty} p(\mathbf{r}|\mathbf{s}, t) dt \quad [7]$$

where Q is the mass emission rate of particles, and $p(\mathbf{r}|\mathbf{s}, t)dV$ is the probability that a particle released at ' s ' will be found in a volume dV surrounding ' r ' after a travel time t from release. Then, the problem of calculating the concentration reduces to estimating the probability density function, $p(\mathbf{r}|\mathbf{s}, t)$, of particle positions as a function of travel time from the source. A good approximation for this function is the Gaussian distribution. Placing the origin of our coordinate system at the source, we can express the distribution as

$$p(\mathbf{r}|\mathbf{s}, t) = \frac{1}{(2\pi)^{3/2} \sigma_x \sigma_y \sigma_z} \times \exp \left(-\frac{1}{2} \left(\frac{(x_r - \bar{x})^2}{\sigma_x^2} + \frac{(y_r - \bar{y})^2}{\sigma_y^2} + \frac{(z_r - \bar{z})^2}{\sigma_z^2} \right) \right) \quad [8]$$

where σ_x , σ_y , and σ_z are the standard deviations of particle positions about their mean positions $\bar{x}$, $\bar{y}$, and $\bar{z}$ after a travel time, t , from release, and x_r , y_r , and z_r are the receptor coordinates. These statistics are derived by averaging over an infinite number of particles for a flow with fixed mean and turbulent characteristics; the statistics are functions of travel time, t .

The probability distribution function, eqn [8], represents an ensemble average over all possible particle positions for a fixed travel time from the source; the travel time is the difference between the arbitrary time at which the particle is released and time at which the particle is observed at a location. In principle, it can be constructed experimentally by releasing particles serially from a source, and recording the coordinates of these particles at specified travel times. Thus, eqn [8] does not

describe the distribution of particle positions within a 'puff,' which usually describes an entity at an instant of time.

To make progress, we need expressions for σ_x , σ_y , and σ_z . While the mean particle positions are determined by the mean flow, the standard deviations depend on the characteristics of the turbulent flow. Taylor derived expressions for the variance of particle positions as a function of travel time from a fixed release point in a steady flow in which turbulent statistics do not depend on location. His expressions for the asymptotic behavior of plume spread are

$$\begin{aligned} \sigma_y &= \sigma_v t \quad \text{for } t \ll T_{Lv} \\ \sigma_y &= \sigma_v (2tT_{Lv})^{1/2} \quad \text{for } t \gg T_{Lv} \end{aligned} \quad [9]$$

where T_{Lv} is the Lagrangian timescale, which can formally defined in terms of the statistics of the turbulent flow. For our purposes, it is sufficient to interpret the timescale as roughly the time over which a particle retains its initial velocity. For small travel times, a particle's velocity remains essentially unchanged from its value at the release point, and the particle trajectory is a straight line. This explains the result that, for small travel times, the spread of particles is proportional to the travel time from the source (eqn [9]). On the other hand, when the travel time is large compared to the Lagrangian timescale, the plume spread is proportional to the product of the 'average' step size, $\sigma_v T_{Lv}$, and the square root of the number of steps, t/T_{Lv} , taken by the particle.

In order to obtain an expression for the concentration, we still have to integrate eqn [7] after inserting eqn [8] with appropriate expressions for plume spread. Let us first consider an idealized flow that is used to model dispersion in the atmospheric boundary layer. In this flow, the mean wind U is along the x -axis, and the turbulence is homogeneous and stationary. These assumptions lead to

$$\bar{x} = Ut, \quad \bar{y} = 0, \quad \text{and} \quad \bar{z} = 0 \quad [10]$$

If we make the assumption that along-wind dispersion, σ_x , is small compared to transport by the mean wind, the

exponential term in eqn [8], associated with downwind dispersion, becomes a Dirac delta function in the limit of σ_x going to zero. This allows us to integrate eqn [7] for arbitrary σ_y and σ_z to obtain

$$C(\mathbf{r}) = \frac{Q}{2\pi\sigma_y\sigma_zU} \exp\left(-\frac{1}{2}\left(\frac{y^2}{\sigma_y^2} + \frac{z^2}{\sigma_z^2}\right)\right) \quad [11]$$

where the plume spreads are evaluated at $t = x/U$. This equation is identical to the empirical expression presented earlier. We can obtain an expression for the concentration even when downwind dispersion is not small if we can express plume spreads in terms of the asymptotic limits of eqn [9].

Observations of plume spread from elevated releases are often summarized in the form

$$\sigma_y = \frac{\sigma_{yt}}{(1 + t/2T_{Lv})^{1/2}} \quad [12]$$

to ensure consistency with theory of eqn [9]. For ground-level releases, there is no simple way of relating travel time to distance because the velocity varies rapidly with height near the ground. Under these circumstances, we need to use methods that are discussed next.

Dispersion in an Inhomogeneous Boundary Layer

The theory presented thus far applies to a boundary layer in which the mean and turbulent properties are constant in space and time. To apply it to a real boundary layer in which the properties are highly inhomogeneous, we can use one of two approaches. The first is to average the turbulence and mean properties over the region of interest, and use the average properties in the (homogeneous) formulations discussed earlier. This is the most straightforward approach, except that the averaging procedure is necessarily arbitrary. The validity of the method needs to be established by comparing the results obtained from the formulations with observations or theory that accounts for inhomogeneity more explicitly. In general, empirical knowledge derived from observations plays a major role in the development of practical models of dispersion. As in most turbulence research, theory can suggest plausible forms for a dispersion model, but the model almost always contains parameters that have to be estimated from observations.

Even if we could treat the boundary layer as vertically homogeneous, the presence of boundaries, such as the ground and the top of the mixed layer, makes it difficult to estimate the Lagrangian timescale, T_{Lv} , from a priori considerations. Thus, the timescale is often treated as an empirical parameter that is derived by fitting eqn [12] to observations. Alternatively, we can postulate an expression for T_{Lv} in terms of a known length scale l as shown in eqn [13].

$$T_{Lv} = \alpha l / \sigma_v \quad [13]$$

The parameter α has to be obtained by fitting estimates of plume spread to observations. In unstable conditions, l , usually scales with the depth of the boundary layer, while in stable conditions, the relevant length scale is taken to be σ_w/N , where N is the Brunt–Vaisala frequency.

The second approach to accounting for inhomogeneity in the boundary layer is based on the solution of the species

conservation equation. Let us examine this approach in some detail because it yields useful results for dispersion in the surface boundary layer.

Solving the Species Conservation Equation

The species conservation equation (eqn [4]) can be rewritten as eqn [14].

$$\frac{\partial C}{\partial t} + \frac{\partial}{\partial x_i}(U_i C) = \frac{\partial}{\partial x_i}(\overline{u_i c}) + D \frac{\partial^2 C}{\partial x_i \partial x_i} \quad [14]$$

One way of modeling the turbulent flux term is to postulate the concept of eddy diffusivity. It is based on an analogy with molecular diffusion, in which the flux of material in any direction is proportional to the gradient of the concentration. For example, the turbulent flux of species is according to eqn [15], where K_i is the so-called eddy diffusivity.

$$\text{turbulent flux} = \overline{u_i c} = -K_i \frac{\partial C}{\partial x_i} \quad [15]$$

where the bar over i negates the summation convention. This relationship cannot be justified rigorously for turbulent transport. However, it has heuristic value, and is useful for developing semiempirical models of turbulent transport. The use of the eddy diffusivity in the mass conservation equation is often referred to as K -theory.

With eqn [15], eqn [14] can be rewritten in the form of eqn [16],

$$\frac{\partial C}{\partial t} + \frac{\partial}{\partial x_i}(U_i C) = \frac{\partial}{\partial x_i}\left(K_i \frac{\partial C}{\partial x_i}\right) \quad [16]$$

where we have neglected the molecular diffusion term in comparison to turbulent diffusion. While molecular diffusion can often be ignored in calculating the ensemble mean, it plays a major role in determining the statistics of concentration fluctuations, as we will see later.

One way of checking whether the use of the eddy diffusivity is plausible is to see whether eqn [16] yields solutions that are compatible with observations. We will apply eqn [16] to the point source problem. If we assume that transport along the mean wind dominates over the corresponding diffusion term, and turbulent properties are homogeneous, eqn [16] can be reduced to the form given by eqn [17].

$$U \frac{\partial C}{\partial x} = K_z \frac{\partial^2 C}{\partial z^2} + K_y \frac{\partial^2 C}{\partial y^2} \quad [17]$$

It turns out that eqn [17] yields the empirical Gaussian solution of eqn [5] if we ensure that the eddy diffusivity is related to the plume spread according to eqn [18].

$$K_i = \frac{1}{2} U \frac{d\sigma_i^2}{dx_i} \quad [18]$$

If we take plume spread to follow the behavior described in eqn [9], we see from eqn [18] that the eddy diffusivity is proportional to the travel time, x/U , from the source, for travel times less than the governing Lagrangian timescale. What this means is that the eddy diffusivities corresponding to two different sources displaced along the wind will have different values at the same location. It is only at large travel times that

eddy diffusivities become independent of travel time (eqn [19]), where T_{Lv} and T_{Lw} are the Lagrangian timescales for the horizontal and vertical velocity fluctuations, respectively.

$$K_y = \sigma_v^2 T_{Lv} \quad \text{and} \quad K_z = \sigma_w^2 T_{Lw} \quad [19]$$

The eddy diffusivity, K_z , can be related to turbulent flow properties by appealing to 'mixing length' theory, which suggests the relationship [20], where σ_w is the standard deviation of the vertical velocity fluctuations, and l_z is the 'length scale' of turbulence for vertical transport, defined by eqn [21], which is consistent with eqn [13].

$$K_z = \sigma_w l_z \quad [20]$$

$$l_z = \sigma_w T_{Lw} \quad [21]$$

We are now in a position to make some additional statements on the applicability of the eddy diffusivity concept. We saw earlier that eqn [19] is valid when the travel time is much larger than the Lagrangian timescale, expressed by the relationship [22].

$$t = \frac{x}{U} \gg T_{Lw} \quad [22]$$

If we combine this condition with the expression for plume spread, eqn [9], and use eqn [21], we obtain eqn [23].

$$\sigma_z \gg l_z \quad [23]$$

Thus, the eddy diffusivity concept is most applicable when the scale of concentration variation, σ_z , is much larger than the scale of the eddies responsible for plume spreading.

Equation [20] is useful because we can guess at the appropriate form of l_z , and then see whether the consequences of our assumption agree with observations. Over the years, we have developed enough experience with different types of flows to prescribe useful forms for the mixing length (or eddy diffusivity) for these flows. Our initial guesses for K are usually based on measurement of fluxes and the associated gradients for a limited set of situations. This K is then extrapolated to situations different from those used to derive it. For example, we can derive a K for heat flux, and find out whether it works for pollutant transport. It is this type of semiempirical arguments that form the basis of practical calculations for turbulent flows.

Equation [15] represents only one possible approach to expressing the turbulent flux. In principle, we can write conservation equations for the turbulent fluxes, but these equations contain 'third-order' terms that are essentially the fluxes of the second-order terms. These third-order terms have to be parameterized using some sort of flux-gradient approximation. At this point, there is no compelling evidence to suggest that these approaches yield much better results than the closure of eqn [15]. One way of improving upon a simple prescription of the eddy diffusivity is to formulate semiempirical conservation equations for the components of eddy diffusivities: the turbulent velocity and the length scale in eqn [20]. In practice, the turbulent velocity is related to the turbulent kinetic energy, k , and the length scale is related to the turbulent dissipation rate, ε . While the $k - \varepsilon$ approach is popular in modeling turbulent flows, it has found limited application in modeling dispersion.

The eddy diffusivity formulation is almost exclusively used in comprehensive Eulerian air quality models that include details of atmospheric process such as gas- and aqueous-phase chemistry. The main reason is that the species conservation equation, formulated in terms of the eddy diffusivity, is a convenient framework to incorporate a number of processes, including nonlinear chemistry. The resulting mass conservation can be solved using numerical methods. Results from comprehensive air quality models indicate that modeling dispersion with the eddy diffusivity model has some practical value, even though the underlying theoretical justification is weak.

We saw earlier that the eddy diffusivity concept is likely to be most applicable when the turbulent length scales are smaller than or comparable to the concentration space scales. Thus, we might expect it to apply to dispersion in the surface boundary layer, where plume spread in the vertical spread is comparable to the length scale of the eddies responsible for vertical transport. It turns out that K -theory provides useful results for dispersion in the surface boundary layer even though it is characterized by steep gradients in temperature and velocity. However, the gradients of fluxes and turbulence levels are negligible. In the surface boundary layer, semiempirical theories, referred to as Monin-Obukhov similarity, provide useful relationships between velocity and temperature gradients and the corresponding heat and momentum fluxes. These relationships are cast in terms of length and velocity scales, which are the surface friction velocity u_* and the Monin-Obukhov length, L , defined by eqns [24],

$$u_* = \sqrt{\frac{\tau}{\rho}} \quad [24]$$

$$L = -\frac{T_0 u_*^3 \rho C_p}{g \kappa H_0}$$

where τ is the surface shear stress, ρ is the air density, C_p is the specific heat of air, T_0 is the surface temperature, κ is the von Karman constant, g is the acceleration due to gravity, and H_0 is the surface heat flux. These relationships can be used to derive eddy diffusivities for heat and momentum.

Using the eddy diffusivity for heat in the mass conservation equation has provided concentration estimates that compare well with observations made in field experiments conducted in Prairie Grass, Nebraska, in the 1950s. We note that data from this experiment, conducted with relatively primitive equipment, are still the most complete for the analysis of surface layer dispersion.

The solutions of the mass conservation equations, using the eddy diffusivity, have a number of useful asymptotic forms for the crosswind-integrated concentration, $\bar{C}'$, as shown by eqn [25], where $\bar{x} = x/|L|$, $\bar{C} = \bar{C}' u_* |L| / Q$, with Q representing the source strength. These asymptotic forms are useful because they can be patched together to obtain analytic expressions that span the entire range of stability. Unknown parameters in these expressions have been obtained by fitting them to observations from Prairie Grass.

$$\begin{aligned} \bar{C} &\sim \bar{x}^{-1} \text{ for neutral conditions} \\ &\sim \bar{x}^{-2/3} \text{ for stable conditions} \\ &\sim \bar{x}^{-2} \text{ for unstable conditions} \end{aligned} \quad [25]$$

These expressions for crosswind-integrated concentrations can be converted to yield centerline concentrations through

eqn [26], where σ_y is the crosswind spread, and the crosswind distribution is taken to be Gaussian.

$$C(x, y, 0) = \frac{\bar{C}'}{\sqrt{2\pi}\sigma_y} \exp\left(-\frac{y^2}{2\sigma_y^2}\right) \quad [26]$$

Equation [25] can be used to derive expressions for the vertical plume spread. These expressions depend on distance from the release location because travel time has little meaning near the ground. In fact, most dispersion models used in practical applications express the concentration in terms of a Gaussian distribution, where the plume spreads are empirically derived functions of source–receptor distance and micrometeorology.

Puff Dispersion

In the preceding sections, we have discussed dispersion of plumes, which refers to a continuous release from a source. Often we are interested in concentrations associated with puffs of material that are released almost instantaneously, as in an explosion. The concentration of material in the plume is determined by the spread of the material about the center of mass of the moving puff. The analysis of such puffs is more complicated than that of plumes because the spread depends on both space and time correlations between particles in the puff; as Taylor's analysis indicates, plume dispersion can consider the motion of particles to be independent of each other. These space–time correlations depend on the properties of the turbulent eddies that contribute to puff spread at any instant of time. The length scale of the relevant eddies is roughly proportional to the size of the puff. Eddies smaller than this length scale disperse the material within the puff, while eddies larger than the puff transport the puff as a whole.

When the puff size is of the order of the Kolmogorov microscale, the puff spreads by molecular diffusion, which implies that the puff spread, s , is proportional to the square root of time. When the puff size is comparable to eddies in the inertial subrange, dimensional considerations suggest that the rate of puff spread is represented by eqn [27], where ε is the dissipation rate of turbulent kinetic energy.

$$\frac{ds}{dt} \sim (\varepsilon s)^{1/3} \quad [27]$$

Integration yields expression [28].

$$s \sim \varepsilon^{1/2} t^{3/2} \quad [28]$$

This rapid growth phase ends when the puff size is comparable to the largest eddy of dimension L . Then, the puff spread can be written as [29], where σ_v refers to the standard deviation of the turbulent velocity fluctuations in the direction of the spread.

$$s \sim (\sigma_v L)^{1/2} t^{1/2} \quad [29]$$

These three regimes of puff growth can, in principle, be patched together to provide a continuous description of puff spread. But this is rarely done in practice, and one usually resorts to empirical descriptions of puff spread. The actual concentration in a puff is usually estimated with a Gaussian distribution about the puff center of mass.

The simplest puff model is the Gaussian puff model that relates concentration at receptor (x, y, z) at time t due to a puff released from origin at time 0 by eqn [30], where Q_m is the total mass of the puff and s is the puff spread corresponding to the Gaussian distribution.

$$C(x, y, z, t) = \frac{Q_m}{(2\pi)^{3/2} s^3} \exp\left[-\frac{(x - Ut)^2 + y^2 + z^2}{2s^2}\right] \quad [30]$$

In practical applications, a continuous release in a wind field that varies in space and time can be modeled through a series of puffs, each of which is allowed to follow a different trajectory. The concentration at a receptor at any given time is calculated by summing the contributions from these puffs. One advantage of this approach is that it can deal with situations when the mean wind is calm.

Dispersion of Heavy Particles

The previous discussions implicitly assumed that the material being dispersed by turbulence has the same density as air. This assumption is clearly not valid for aerosol particles, whose densities are typically over 1 g cm^{-3} . Two effects influence dispersion of such particles. One is related to the finite time required by the particle to respond to turbulent velocity fluctuations. The other is the so-called trajectory crossing effect related to particle trajectories being different from fluid parcel trajectories because of gravitational settling. Let us consider each of these effects.

The particle inertia effect is related to the difference between the fluid velocity, u_f , and the particle velocity, u_p , whose difference is proportional to the reaction time to turbulent velocity fluctuations. This can be expressed symbolically by eqn [31], where the relaxation timescale of the particle is given by eqn [32].

$$\frac{(u_f - u_p)}{u_f} \sim \frac{\tau_{\text{particle}}}{\tau_{\text{turbulence}}} \quad [31]$$

$$\tau_{\text{particle}} \sim \frac{w_s}{g} \quad [32]$$

Here, w_s is the gravitational settling velocity, which is a function of the size and density of the particle and the viscosity of the fluid. The turbulence timescale can be expressed as [33], where l is a measure of eddy size and σ_w is the associated velocity fluctuation.

$$\tau_{\text{turbulence}} \sim \frac{l}{\sigma_w} \quad [33]$$

Thus, inertia effects can be neglected if the ratio of these two scales is small (see eqn [34]).

$$\frac{w_s \sigma_w}{gl} \ll 1 \quad [34]$$

If we take small to mean 0.1, and consider $100 \text{ }\mu\text{m}$ particles with settling velocities of the order of 1 m s^{-1} , and take the turbulent velocity to be 1 m s^{-1} , the inertia effect is not likely to be important for length scales greater than 1 m . However, it could play a role in the dispersion of large particles under very stable conditions, close to the ground.

Figure 2 Timescales that affect dispersion of heavy particles.

The trajectory crossing effect can be examined by considering the extreme case when the time taken for a falling particle to traverse an eddy is much smaller than the Lagrangian timescale for vertical dispersion. Then, the effective Lagrangian timescale becomes this traversal time because it corresponds roughly to the decorrelation time. The effective Lagrangian timescale and the associated eddy diffusivity for the heavy particle can now be represented by eqn [35].

$$\tau_{\text{Leff}} = \frac{l}{w_s} \quad \text{and} \quad K_{\text{eff}} = \frac{\sigma_w^2 l}{w_s} \quad [35]$$

Figure 2 shows the timescales that govern dispersion of heavy particles. In practice, the effects of particle settling are not important in determining plume spread because settling velocities for most particles are generally much smaller than turbulent velocities. However, even particle velocities of the order of a few centimeters per second lead to mean downward motion of the plume, and hence increase concentrations at ground level. This effect can be described approximately by ‘tilting’ the plume toward the ground, represented by eqn [36].

$$h_s(\text{with particles}) = h_s - \frac{w_s x}{U} \quad [36]$$

Alternatively, the entire concentration profile can be moved ‘into’ the ground by a distance $w_s x/U$ after computing the concentration corresponding to passive dispersion. It is simple to account for mean motion of particles in the eddy diffusivity formulation through the advection term, $w_s(\partial C/\partial z)$.

Other Approaches to Modeling Dispersion

The eddy diffusivity approach does not generally apply to sources far removed from the ground. For example, it is difficult to justify its application to the convective atmospheric layer, where the turbulent length scales are large compared to the spatial scales of the concentration field. The pdf approach can provide useful results under these circumstances. Studies show that dispersion in the CBL is strongly influenced by the relative longevity of convective downdrafts and updrafts. The majority of particles released in downdrafts travel continuously downward until they

reach the vicinity of the ground. Numerical experiments indicate that to a useful degree of approximation, the velocity of these particles can be taken to be constant at the value at the release point.

This assumption allows one to express the crosswind-integrated ground-level concentration, $\bar{C}^y$, in terms of the pdf of the vertical velocity, $p(w|h_s)$, at the height of release, h_s , by eqn [37], where the vertical velocity corresponds to that required to bring material from the release point to the ground-level receptor at x , given by [38].

$$\bar{C}^y = \frac{2Q}{x} P(w|h_s) \quad [37]$$

$$w = -Uh_s/x \quad [38]$$

The simple formulation, which can be readily modified to account for the presence of the mixed layer, provides an excellent description of laboratory observations of dispersion in the CBL. Note that eqn [37] reproduces the empirical Gaussian distribution if we make the reasonable assumption that the pdf of vertical velocity fluctuations is normal, giving eqn [39], where σ_z is expressed by eqn [40].

$$\bar{C}^y = \sqrt{\frac{2}{\pi}} \frac{Q}{U\sigma_z} \exp\left[-\frac{h_s^2}{2\sigma_z^2}\right] \quad [39]$$

$$\sigma_z = \sigma_w x/U \quad [40]$$

The Gaussian formulation is not reliable in the CBL because the pdf is positively skewed. The associated negative mode of the pdf leads to the descent of the plume centerline when the release is elevated, and leads to concentrations that are about 30% higher than that predicted with the Gaussian formulation.

In principle, if we could simulate all the scales of turbulent motion, there would be no need for models of turbulent dispersion. We could use the Navier–Stokes equations to generate an ensemble of flows, obtain the corresponding concentration fields from the species conservation equation, and average over them to obtain the ensemble average as well as the statistics of concentration fluctuations. With the rapid increases in computing power, direct numerical simulation (DNS) is becoming a reality, and we have been able to obtain useful information for low Reynolds number flows. However, it will be some time in the future before we will be able to use the technique for routine applications.

The large eddy simulation (LES) technique avoids the computational demands of DNS by only simulating the energy-containing eddies. The effects of the unresolved scales of motion are modeled using a variety of parameterizations. It is believed that the most important features of flow are insensitive to these parameterizations, because the subgrid scales contain a small fraction of the total energy. This assumption has been vindicated by LES of CBLs that was pioneered by Deardorff in the 1970s. Velocity fields generated by LESs compare well with observations, and continue to provide information that is difficult to obtain in the field. Lamb used the velocity fields generated by Deardorff to simulate dispersion in the CBL. The simulation consisted of releasing a large number of particles and tracing their motion using the LES velocity field. Then, the crosswind concentration averaged over

Figure 3 Calculation of concentrations using Lagrangian stochastic simulation of particle trajectories.

a vertical distance Δz is given by eqn [41], where f is the fraction of the particles released that pass through Δz .

$$\bar{C}^y = \frac{Q}{U \Delta z} f \quad [41]$$

Figure 3 justifies this equation.

Lamb's simulations provided valuable insight into dispersion in the CBL, including the observation that the locus of the maximum concentration descended toward the ground. This behavior is related to the negative mode of the pdf of the vertical velocity fluctuations.

A technique that is not as computationally demanding as DNS or LES is called Lagrangian stochastic simulation (LSS). It is attractive because it only uses the statistics of the velocity field such as velocity variance, and dissipation rate of turbulent kinetic energy. Because this technique is being used to examine routine dispersion problems, we discuss it in some detail in the next section.

Lagrangian Stochastic Models

In Lagrangian stochastic modeling, turbulent dispersion is modeled by tracing the motion of a large number of fluid particles that are tagged at the source; these particles are treated mathematically as points. The evolution of the velocity of each particle depends on turbulence properties at the current location of the particle. To illustrate the basic ideas, let us trace a particle that is only affected by vertical velocity fluctuations. Then, the vertical velocity of a parcel at time $t + \Delta t$ is related to the velocity at time t through eqn [42], where w' is a random velocity drawn from the distribution of vertical velocity fluctuations.

$$w(t + \Delta t) = \alpha w(t) + \beta w' \quad [42]$$

Thus, the future velocity of the particle consists of a deterministic component that depends on its current velocity, and a random component that depends on the turbulence at the location of the particle. We can show that

eqn [42] is equivalent to the Langevin equation in which a particle is subject to a linear viscous force and a random pressure force.

The particle position is traced through eqns [43].

$$\begin{aligned} \Delta z &= w(t + \Delta t) \Delta t \\ \Delta x &= U \Delta t \end{aligned} \quad [43]$$

In homogeneous turbulence, we can show that α and β are given by eqns [44],

$$\alpha = \left(1 - \frac{\Delta t}{T_{Lw}}\right) \quad \text{and} \quad \beta = \left(\frac{2 \Delta t}{T_{Lw}}\right) \quad [44]$$

where the Lagrangian timescale, T_{Lw} , can be related to the turbulent dissipation rate according to eqn [45], where C_0 is a constant.

$$T_{Lw} = \frac{2 \sigma_w^2}{C_0 \varepsilon} \quad [45]$$

While this simple model has produced useful results, it is not applicable to boundary layers with gradients in turbulence properties. New developments in LSS are best described by recasting eqn [42] as eqn [46], where a is given by eqn [47], and the $d\zeta$ is a normal random variable with zero mean and variance dt .

$$dw = aw \, dt + (C_0 \varepsilon)^{1/2} d\zeta \quad [46]$$

$$a = \frac{C_0 \varepsilon}{2 \sigma_w^2} \quad [47]$$

During the 1980s, several ad hoc formulations for the term ' a ' in eqn [46] were proposed to account for flow complexities such as inhomogeneity and non-Gaussianity of the turbulent velocities. This unsatisfactory situation was remedied by Thomson in 1987 when he proposed a systematic method for constructing formulations for ' a ' by invoking the constraint that the model for this term should preserve a well-mixed concentration field. This is equivalent to insisting that the Lagrangian pdf for fluid particles marked at the source should become identical to that of unmarked fluid particles at large travel times. The evolution of the pdf is governed by the Fokker-Planck equation corresponding to eqn [46]. Using the solution of this equation, Thomson was able to derive formulations for the term ' a ' that accounted for inhomogeneity and non-Gaussianity of the turbulent velocities. For example, the modified form of eqn [46] can be represented by eqn [48].

$$dw = -\frac{C_0 \varepsilon}{2 \sigma_w^2} w \, dt + \frac{1}{2} \left(1 + \frac{w^2}{\sigma_w^2}\right) \frac{\partial \sigma_w^2}{\partial z} dt + (C_0 \varepsilon)^{1/2} d\zeta \quad [48]$$

It turns out that ' a ' can be expressed uniquely only for one-dimensional turbulence or isotropic turbulence; for two- and three-dimensional turbulent flows, ' a ' is not a unique function of the velocity field. This nonuniqueness problem can be serious because for a given turbulent flow, substantially different concentration fields can be obtained from two models, both of which satisfy the well-mixed condition.

One way of alleviating this problem is to drive Lagrangian stochastic models with velocity fields obtained from large eddy simulation because large eddies that contribute to inhomogeneity and anisotropy of the velocity field are treated explicitly in both LES and LSS. The subgrid-scale eddies can be considered

locally homogeneous and locally isotropic. Because only the particle motion associated with subgrid energy is modeled with LSS, errors associated with the nonuniqueness of the LSS model can be minimized.

Concentration Fluctuations and Model Uncertainty

Any given observed concentration will deviate from the ensemble average. This deviation is caused by the intrinsic variability of the concentration field called concentration fluctuations. In principle, the statistics of these concentration fluctuations can provide insight into the expected deviation of the model-predicted ensemble mean from a corresponding observed concentration.

To understand the effect of concentration fluctuations, consider the following model of the concentration time series in which the concentration is a peak value, C_{peak} , or zero. Then, we can show that the variance of the instantaneous concentration about the ensemble-averaged mean is given by eqn [49].

$$\frac{\sigma_c^2}{C^2} = \frac{C_{\text{peak}}}{C} - 1 \quad [49]$$

Because the peak-to-mean concentration ratio can be as large as 10 or even 100, especially close to an elevated source, the standard deviation of the concentration fluctuations can be several times the mean. If we are interested in predicting a time-averaged concentration, we have to estimate the timescale, T_c that governs the concentration fluctuations. This then allows us to estimate the number of independent concentration events that we are likely to observe during the averaging interval T_{av} , as T_{av}/T_c . Then, the deviation, δ , of the time-averaged mean about the ensemble mean is given by eqn [50].

$$\frac{\delta}{C} \sim \left[\frac{T_c}{T_{\text{av}}} \right]^{1/2} \frac{\sigma_c}{C} \quad [50]$$

T_c roughly corresponds to the time taken for the instantaneous plume to pass a fixed observer. If we take the instantaneous plume size to be 100 m and the wind speed to be 5 m s^{-1} , the timescale, T_c , is 20 s. Assuming that we are interested in an averaging time of 1 h, δ works to be about 25% of the mean for a peak-to-mean ratio of 10. This exercise identifies the variables that might govern the deviation between model estimates and observations. Actual comparisons between model estimates and observations indicate that the error is much larger because of model formulation and input errors. A model is generally considered adequate if its estimates are consistently within a factor of two of the observations.

We can use a simple model to discuss the role of molecular diffusion in determining concentration fluctuations. Assume that we release Q_m mass units in an initial volume of V_0 , so that the initial concentration is Q_m/V_0 . As the released material is stretched over a larger volume, V , in space, the volume marked by the material remains unchanged if the fluid is incompressible and molecular diffusion is negligible (see Figure 4). The mean concentration, corresponding to material spread over V , is proportional to $1/V$, while the peak concentration remains unchanged from the initial value. Then, the peak-to-mean ratio, which determines the concentration variance, is simply V/V_0 . In the presence of molecular diffusion, the material is no longer confined to its initial volume, and the peak concentration has to decrease with time. Thus, molecular diffusion decreases concentration fluctuations relative to the mean value.

The meandering plume model, used to estimate the variance of concentration fluctuations, is an extension of the previous concept. Here, the time-averaged plume is assumed to be composed of instantaneous plumes whose dimensions are determined by relative dispersion. Then, the peak concentration is determined by the concentration within the instantaneous plume, which is inversely proportional to s^2 , where s refers to the spread by relative dispersion. Then, if σ is the time-averaged spread of the plume, the peak-to-mean ratio, and the

Figure 4 Factors that affect concentration fluctuations. $C_{\text{peak}} \sim C_0$ in the absence of molecular diffusion, and $\sigma_c^2/C^2 \sim C_{\text{peak}}/C \sim V/V_0$.

normalized concentration variance is of the order of σ^2/s^2 as long as we can neglect molecular diffusion within the instantaneous plume. Molecular diffusion will eventually smear the concentration over the instantaneous plume and thus decrease the normalized concentration variance.

The statistics of concentration fluctuations can be used in estimating the air quality impacts of species for which small time exposures are important. These statistics can be used to estimate the probability that a certain threshold is exceeded. Thus, there is great interest in formulating models for concentration fluctuations. Some of the more recent models have combined a version of LSS with LES velocity fields to model relative dispersion and thus concentration fluctuations. In the future, we are likely to see more use of DNS in understanding turbulent dispersion. This does not mean that our ability to predict concentrations will improve substantially, because the nature of turbulence places practical limits on predicting individual realizations of concentrations.

Synopsis

Marine meteorology is a subfield of meteorology, which deals with the weather and climate as well as the associated ocean conditions in marine, island, and coastal environments. Marine meteorologists collect and analyze weather and oceanographic data, make marine weather forecasts, and provide marine meteorological services to support marine and coastal activities, including but not limited to shipping, fishing, tourism, offshore oil drilling and mining operations, oil spill control, offshore wind and tidal energy harvesting, search and rescue at sea, and naval operations. The interactions between the atmosphere and the ocean create a unique dynamical framework for the fundamental principles of marine meteorology, and the need for employing air–sea coupled models for marine weather prediction.

Introduction

Marine meteorology is a subfield of meteorology, which deals with the weather and climate as well as the associated oceanographic conditions in marine, island, and coastal environments. The physical and dynamical foundations of marine meteorology are no different from other areas of meteorology, but the fundamental processes, which distinguish marine meteorology from other subfields of meteorology are the interactions between the ocean and the atmosphere. Therefore, the part of the physical oceanography dealing with the upper and coastal oceans, which are directly affected and influenced by weather is also considered an integral component of marine meteorology.

Marine meteorology is also unique in that it is a science geared toward the understanding and production of weather information in support of marine and coastal activities, including shipping, fishing, tourism, offshore oil drilling and mining operations, oil spill control, offshore wind and tidal energy harvesting, search and rescue at sea, and naval operations.

The physical processes associated with marine weather encompass not only complex marine environments from the open ocean to the coastal zone and from islands to marginal seas, but also broad dynamic scales. Small-scale phenomena

include turbulence and eddies that occur within the boundary layers on both sides of the air–sea interface. These small-scale features play a major role in determining the air–sea momentum and heat and moisture fluxes that, in turn, affect the atmospheric and oceanic processes at other scales. At meso- and synoptic scales, marine meteorology deals with phenomena such as coastal fronts, coastal low-level jets, land–sea breezes, coastal and sea fogs, coastal cyclones and tropical cyclones (including hurricanes and typhoons), as well as hazardous ocean conditions including storm surge, wind waves, and rip currents. At large and global scales, marine meteorology deals with the weather and climate associated with seasonal, intraseasonal, and interannual variability in maritime environment, such as monsoons, trade wind systems, Madden–Julian oscillation, and El Niño/Southern Oscillation.

In the following, we will present the fundamental principles of marine meteorology and describe the observation, prediction, and application systems of marine weather and climate.

Fundamental Principles

Marine meteorology deals with two forms of geophysical fluids, the atmosphere and the ocean. Therefore, the fundamental physical principles for marine meteorology include the

conservation laws and governing equations for the motions of both geophysical fluids and their interactions. The conservation laws include the conservations of mass, momentum, and energy. The governing equations for atmosphere can be expressed as (Holton and Hakim, 2012):

$$\frac{D\mathbf{U}}{Dt} = -2 \times \boldsymbol{\Omega} \times \mathbf{U} - \frac{1}{\rho} \nabla p + \mathbf{g} + \mathbf{F}_r \quad [1]$$

$$\frac{D\rho}{Dt} + \rho \nabla \cdot \mathbf{U} = 0 \quad [2]$$

$$c_v \frac{DT}{Dt} + p \frac{D\alpha}{Dt} = J \quad [3]$$

$$p = \rho RT \quad [4]$$

where $\mathbf{U}$ is the three-dimensional velocity vector, $\boldsymbol{\Omega}$ is the angular velocity of the earth, ρ is air density, α is specific volume, p is air pressure, $\mathbf{g}$ is gravity (vector variable), $\mathbf{F}_r$ is frictional force, T is air temperature, J is the heating rate due to radiation, conduction, and latent heat release, c_v is the specific heat at constant volume, and R is the gas constant for dry air.

The governing equations for ocean circulation are similar to those for the atmosphere. Ignoring any source/sink terms, the nonhydrostatic primitive equations for the ocean can be written as (Haidvogel and Beckmann, 1999):

$$\frac{D\mathbf{V}}{Dt} = -2 \times \boldsymbol{\Omega} \times \mathbf{V} - \frac{1}{\rho} \nabla p + \mathbf{g} + \nabla \cdot \boldsymbol{\tau} \quad [5]$$

$$\frac{D\rho}{Dt} + \rho \nabla \cdot \mathbf{V} = 0 \quad [6]$$

$$\rho c_p \frac{DT}{Dt} - \beta T \frac{Dp}{Dt} = 0 \quad [7]$$

$$\frac{DS}{Dt} = 0 \quad [8]$$

$$\rho = \rho(T, S, p) \quad [9]$$

Here, $\mathbf{V}$ is the current velocity vector, p is pressure, ρ is water density, T is water temperature, S is salinity, $\mathbf{g}$ is gravity, $\boldsymbol{\tau}$ is the stress tensor, c_p is the specific heat of water at constant pressure, and β is the thermal expansion coefficient $-\frac{1}{\rho} \left(\frac{\partial \rho}{\partial T} \right)_p$.

Sea surface waves are ubiquitous at ocean surface, with air and water on each side of the air-sea interface. The dynamics of surface waves is also determined by the Navier-Stokes equation for a two-layer fluid. It is so complicated that one cannot solve it directly either analytically or numerically. Fortunately, the density of air is much smaller than that of water. Sea surface waves can be described in good approximation by the linearized Navier-Stokes equations for a one-layer fluid in a gravitational field (Komen et al., 1994):

$$\frac{\partial \mathbf{u}}{\partial t} = -\frac{1}{\rho} \nabla p \quad [10]$$

$$\frac{\partial w}{\partial t} = -\frac{1}{\rho} \frac{\partial p}{\partial z} - g \quad [11]$$

$$\nabla \cdot \mathbf{u} + \frac{\partial w}{\partial z} = 0 \quad [12]$$

$$\frac{\partial \eta}{\partial t} = w, z = 0 \quad [13]$$

$$p = p_{\text{atm}}, z = 0 \quad [14]$$

where $\mathbf{u}$ is the horizontal velocity vector, w is the vertical velocity component, and p_{atm} is the air pressure at the sea surface. Assuming wavelike solutions, one can obtain the dispersion relation for sea surface waves:

$$\omega_{\pm} = \pm \sigma, \sigma^2 = gk \tanh kh \quad [15]$$

where ω is the wave frequency, k is wave number, g is the scalar variable, and h is water depth. The general solution can then be expressed as

$$\begin{pmatrix} \eta \\ \mathbf{u} \\ w \\ p + \rho g z \end{pmatrix} = a \begin{pmatrix} 1 \\ \omega_{\pm} \mathbf{k} / k e^{kz} \\ -i \omega_{\pm} e^{kz} \\ \rho g e^{kz} \end{pmatrix} e^{i(\mathbf{k} \cdot \mathbf{x} - \omega_{\pm} t)} + \text{c.c.} \quad [16]$$

in which, a is an arbitrary constant and c.c. is the complex conjugate term. In reality, sea surface waves can be thought of as a superposition of many such linear waves. However, in practice one never considers the deterministic initial value problem for a realistic sea basin, because it is virtually impossible to determine the correct phases for the wave components. Instead, we resort to the homogeneous and stationary statistical theory of linear random waves and introduce wave spectrum $F(\mathbf{k}, \mathbf{x}, t)$ and wave action $N(\mathbf{k}, \mathbf{x}, t) = F(\mathbf{k}, \mathbf{x}, t) / \sigma(\mathbf{k}, \mathbf{x})$, which characterize the statistical properties of sea surface waves, to describe the wave energy and its propagation and dissipation. The wave action balance equation can be written as (Komen et al., 1994):

$$\left\{ \frac{\partial}{\partial t} + (\mathbf{c}_g + \mathbf{U}) \cdot \frac{\partial}{\partial \mathbf{x}} - [\nabla_{\mathbf{x}}(\sigma + \mathbf{k} \cdot \mathbf{U})] \cdot \frac{\partial}{\partial \mathbf{k}} \right\} N = \frac{S_{\text{in}}}{\sigma} + \frac{S_{\text{nl}}}{\sigma} + \frac{S_{\text{ds}}}{\sigma} + \frac{S_{\text{bot}}}{\sigma} \quad [17]$$

where $\mathbf{U}$ is the background current velocity and $\mathbf{c}_g$ is the wave group velocity. The right-hand side terms are the source terms describing wind input (S_{in}), white-capping dissipation (S_{ds}), bottom friction (S_{bot}), and a nonlinear interaction term (S_{nl}). The above equation is typically adopted as the governing equation for various surface wave models. Surface wave characteristics such as significant wave height can be obtained from the wave action (spectrum).

The above equations form the basic governing equations for the atmosphere, ocean circulation, and sea surface waves. However, these equations are not complete without the relationships governing their interactions. Atmospheric circulation, ocean circulation, and sea surface waves interact through various air-sea exchanges across the air-sea interface, and wave-current interactions within the ocean. The atmosphere and the ocean exchange mass, momentum, and energy, as well as other chemical properties primarily through turbulent fluxes, forming an air-sea coupled system. Parameterizations of these turbulent fluxes are usually either through the bulk formula or through the sea surface roughness lengths. The bulk formula for estimating air-sea momentum (τ), sensible heat (H_s), water vapor (E), and latent heat (H_l) fluxes can be expressed as:

$$\tau = \rho_a C_d U^2 \quad [18]$$

$$H_s = \rho_a c_p C_H U (\theta_s - \theta_a) \quad [19]$$

$$E = \rho_a C_E U (q_s - q_a) \quad [20]$$

$$H_l = L_v E = \rho_a L_v C_E U (q_s - q_a) \quad [21]$$

where U is the surface wind speed relative to the ocean surface currents; θ_a , q_a , and θ_s , q_s are potential temperature and specific humidity in air and at sea surface, respectively; ρ_a is air density; c_p is the specific heat of air at constant pressure; L_v is the latent heat of evaporation; C_d , C_H , and C_E are the air-sea transfer coefficients: the drag coefficient, Stanton number, and Dalton number, respectively. Based on various measurements under low to moderate wind conditions, the drag coefficient usually increases with surface wind, and the Stanton and Dalton numbers are generally weakly dependent upon wind speed. According to the Monin-Obukhov similarity theory, under neutral stable conditions, air-sea transfer coefficients can be related to sea surface roughness lengths:

$$C_d = \kappa^2 \left[\ln \left(\frac{z}{z_0} \right) \right]^{-2} \quad [22]$$

$$C_H = \kappa^2 \left[\ln \left(\frac{z}{z_0} \right) \right]^{-1} \left[\ln \left(\frac{z}{z_T} \right) \right]^{-1} \quad [23]$$

$$C_E = \kappa^2 \left[\ln \left(\frac{z}{z_0} \right) \right]^{-1} \left[\ln \left(\frac{z}{z_q} \right) \right]^{-1} \quad [24]$$

where κ is the Karman constant, z_0 is the sea surface aerodynamic roughness length, and z_T and z_q are the sea surface scalar roughness lengths. Thus, another method to parameterize air-sea fluxes is through these roughness lengths.

Under low to moderate wind conditions, air-sea momentum flux is usually estimated through the Charnock relation (Charnock, 1955):

$$gz_0/u_*^2 = \alpha \quad [25]$$

where u_* is the friction velocity and α is the Charnock parameter which was traditionally thought of as a constant. A constant Charnock parameter means the drag coefficient increases linearly with surface wind, and the effects of sea surface waves are implicitly included in this relation (Guan and Xie, 2004). However, it has been recognized in recent years that sea state including wave state and sea sprays could have important impacts on sea surface wind stress, especially under high wind conditions (Powell et al., 2003; Donelan et al., 2004; Liu et al., 2012; Green and Zhang, 2013).

As for the air-sea heat and moisture fluxes, many field observations show that the air-sea exchange coefficients for sensible heat and water vapor are independent of wind speed, corresponding to the decrease of the scalar roughness parameters with the increasing wind speed. The parameterization of sea surface scalar roughness parameters can be related to sea surface aerodynamic roughness length, e.g., through Coupled Ocean-Atmosphere Response Experiment (COARE) algorithm V3.1 (Fairall et al., 2003):

$$z_T = z_q = \min(1.1 \times 10^{-4}, 5.5 \times 10^{-5} \text{Re}_*^{-0.6}) \quad [26]$$

where $\text{Re}_* = z_0 u_* / \nu$ is the Reynolds number of sea surface aerodynamic roughness. However, under high wind conditions,

as surface wind speed increases, wave breaking and wind tearing of the wave crests disrupt the air-sea interface and generate sea sprays. The existence of sea sprays will, in turn, mediate the air-sea heat and water vapor fluxes, and impact air-sea momentum flux as well, especially under high wind conditions. Recent studies showed that the drag coefficient levels off or even decreases with increasing wind speed under high wind conditions, which is likely due to the existence of sea sprays. Although it is still controversial regarding whether sea sprays have significant impact on air-sea heat and moisture fluxes under low to moderate winds, it is believed that sea sprays have substantial contribution to air-sea heat and moisture transfers under high wind conditions.

Marine Weather Prediction System

A weather prediction system typically contains a data acquisition system, data analysis and assimilation system, a modeling system, and an application product development, dissemination, and decision support system (Figure 1). By collecting quantitative data about the current atmospheric and oceanic states through the observing system, marine weather forecasts predict how the atmospheric and oceanic states will evolve based on scientific understanding of the atmospheric, oceanic, and air-sea interaction processes. What makes marine weather forecasting different from terrestrial weather forecasting is that it provides predictions not only for weather conditions over the ocean and coastal regions, but also for the weather-induced oceanic conditions, such as sea surface waves, rip currents, and storm surge. Thus, a marine weather prediction system consists not only atmospheric but also oceanic observation, forecasting, and application systems as shown in Figure 1.

Marine meteorology and oceanographic observing systems focus on simultaneous observations of meteorological variables above the sea surface and oceanographic variables at and below the sea surface. Table 1 lists the major marine meteorology and oceanographic observation programs coordinated internationally and in the United States. In addition to *in situ* and ground-based observations, remote sensing from satellites of both the atmosphere and the sea surface constitutes a large component of marine meteorology and oceanographic data. These satellites are launched and maintained by international organizations such as the European Space Agency or individual countries such as the United States National Aeronautics and Space Agency, United States National Oceanic and Atmospheric Administration, and China Meteorological Administration.

A marine weather forecast system typically consists of a suite of weather, ocean circulation, and sea surface wave forecast models. Traditionally, these models are stand-alone without taking into account the mutual couplings among them. An atmospheric model predicts weather conditions and provides atmospheric forcing to drive the sea surface wave and ocean circulation models. A sea surface wave model, driven by surface winds from an atmospheric model, provides forecasts for sea states, including significant wave heights and mean wave periods, etc. An ocean circulation model, driven by the atmospheric forcing from an atmospheric model, predicts oceanic conditions including storm surge and inundation as well as

Figure 1 Illustration of a typical marine weather prediction system. XBTs, expendable bathythermographs; AXBTs, airborne expendable bathythermographs; UAVs, autonomous underwater vehicles; MOS, model output statistics.

Table 1 List of major marine meteorology and ocean observation programs

GOOS: GOOS is a permanent Global Ocean Observing System designed to provide observations, modeling, and analysis of surface meteorological and oceanic variables to support operational marine meteorology, climate change, and ocean service applications worldwide (http://www.ioc-goos.org). In the United States, the Integrated Ocean Observing System (IOOS) serves as the US component of GOOS (http://www.ioos.noaa.gov). It is a vital tool for tracking, predicting, managing, and adapting to changes in the US ocean, coastal, and Great Lakes environment. It comprises 11 regional associations. The EuroGOOS is an association of national governmental agencies and research organizations committed to European-scale operational oceanography within the context of GOOS (http://www.eurogoos.org). VOS: The World Meteorological Organization's (WMO) Voluntary Observing Ships (VOSs) scheme collects surface weather data from over 4000 voluntary ships and disseminated to weather service centers worldwide (https://www.wmo.int/pages/prog/amp/mmop/JCOMM/OPA/SOT/vos.html). The US component of VOS (http://www.vos.noaa.gov/vos_scheme.shtml). SOT: The Ship Observations Team under Joint Technical Commission for Oceanography and Marine Meteorology (JCOMM), providing ship-based surface meteorological observations, aero-logical profiles, and subsurface oceanographic observations (http://www.wmo.int/pages/prog/amp/mmop/sot.html). DBCP: The Data Buoy Cooperation Panel was established as a joint WMO/Intergovernmental Oceanographic Commission (IOC) initiative in 1985 to provide data from drifting buoys (Lagrangian drifters), moored buoys (meteorological moorings, tropical moorings, ocean reference stations), as well as ice buoys (http://www.wmo.int/pages/prog/amp/mmop/dbcp.html). GLOSS: The global sea-level network under JCOMM, maintaining the tide gauge network (http://www.wmo.int/pages/prog/amp/mmop/gloss.html). Argo: It is an international program to deploy and maintain a global array of around 3000 autonomous profiling floats measuring the profiles of ocean temperature and salinity to depths of around 2000 m, as well as ocean currents at that depth. Before it becomes operational, Argo is managed by a science team, but once operational, Argo will become a component of the integrated ocean observing system coordinated through JCOMM (http://www.argo.net/). OceanSITES: The Ocean Sustained Interdisciplinary Time-series Environment observation System provides data from deep ocean multidisciplinary reference stations (mainly moored buoys). It is an integral part of GOOS (http://www.oceansites.org/). GHRSSST: The group for high-resolution sea surface temperature (SST) program provides global high-resolution (<10 km) SST products to the operational oceanographic, meteorological, climate, and general scientific community (https://www.ghrsst.org/). NDBC: The United States National Data Buoy Center maintains 103 buoys and 47 fixed C-MAN stations in the oceans and the Great Lakes (http://www.ndbc.noaa.gov/).

sea surface variables. These stand-alone model runs can be considered as one-way coupling among these three model components, without feedback effects being considered.

However, as illustrated in **Figure 2**, the atmosphere, surface waves, and ocean circulation are coupled through air-sea (Kraus and Businger, 1994) and wave-current interaction processes (Xie et al., 2001, 2003). The weather systems are

coupled to the upper ocean mixed layer and surface waves through momentum, heat, and moisture exchanges at the air-sea interface. While the atmospheric forcing drives sea surface waves and underlying ocean currents, ocean exchanges heat and moisture with the atmosphere through air-sea heat and moisture fluxes. The existence of sea surface waves modifies the structures of both the atmospheric and marine boundary

Figure 2 Illustration of a coupled atmosphere–ocean circulation–sea surface wave modeling system. SST, sea surface temperature; SSC, sea surface current; SSS, sea surface salinity. Adapted from Liu, B., Liu, H., Xie, L., Guan, C., Zhao, D., 2011. A coupled atmosphere–wave–ocean modeling system: simulation of the intensity of an idealized tropical cyclone. *Monthly Weather Review* 139, 132–152.

layers, and thus influences air–sea momentum and heat fluxes. Therefore, coupled atmosphere–wave–ocean modeling systems taking into account various air–sea and wave–current interaction processes have been developed and utilized in marine weather forecasting, especially for tropical cyclone systems which are associated with high winds and strongly coupled to the upper ocean mixed layer and surface waves (Liu et al., 2011).

Another important component in the marine weather forecasting system is data assimilation. As the observation system proceeds, various data assimilation techniques, including optimal interpolation, three-dimensional variational method (3DVAR), four-dimensional variational method (4DVAR), and ensemble Kalman filter (EnKF), are utilized to obtain better initial conditions for atmospheric (Zhang et al., 2011), sea surface wave, and oceanic models (Peng et al., 2006). There is also a limitation for the current data assimilation techniques for a coupled air–sea modeling system for marine weather forecasting. Data assimilation techniques are generally only applied to individual model components in a marine weather forecasting system. In this situation, the benefit of adjustments in one model by assimilating observational data can be compromised by errors from the other model (Peng et al., 2007). Unified data assimilation techniques for coupled air–sea modeling systems, which simultaneously assimilate various atmospheric and oceanic observations into coupled air–sea modeling systems are of increasing interest for marine weather forecasting.

In addition, because of the chaotic nature of the atmosphere and ocean, the error in the initial conditions, the massive computational power required, and an incomplete understanding of atmospheric, oceanic, and air–sea interaction processes, numerical prediction model forecasts become less accurate as the forecast time increases. The methods of ensemble forecast and model consensus can help to reduce forecast errors and to identify the most likely outcome.

The historical and near real-time marine weather data along with marine weather and sea state forecasts are disseminated to

various users in marine and coastal environments through international, regional, and national marine weather service centers. As human activities grow in the coastal zone, and as tourism, shipping, fishing, and exploitation of marine resources expand, there is a growing need for the marine meteorological services and information to adequately plan coastal zone marine activities and provide early detection and warning of marine-related hazards.

Synopsis

The field of operational meteorology involves the generation and widespread dissemination of weather information on a consistent and reliable basis. Operational meteorology plays a critical role in the safeguarding of lives and property, as well as providing highly valued information to both general public and commercial enterprises. This article provides an overview of operational meteorology, including the forecast process, information on the structure and function of modern weather services, interactions between the various national and private weather services, and on the interrelationships between operational meteorology and science and technology.

Introduction

Operational meteorology involves the generation and widespread dissemination of weather information on a consistent and reliable basis. In its modern application, this process typically involves the gathering of vast quantities of meteorological observations and execution of complex numerical forecast models, and thus tends to be extremely computer intensive. Operational forecasters examine and interpret the raw numerical forecast output, and use scientific knowledge about how the atmosphere behaves to develop finalized forecast information. This finalized information is disseminated to society, and plays a critical role in the safeguarding of lives and property, as well as providing highly valued information to both general public and commercial enterprises.

The content of the disseminated weather information varies according to the issuing organization and the type of weather information required by its customers; typically, they include gridded, graphical, and narrative forecasts and analyses of weather conditions over particular geographic regions and notification of any anticipated or observed hazardous weather conditions. Although broadcast meteorologists are perhaps the most recognized face of weather information, other forms of dissemination include governmental networks, radio, the Internet, and mobile applications.

This article provides an overview of operational meteorology, including the forecast process, information on the structure and function of modern weather services, interactions between the various national and private weather services, and on the interrelationships between operational meteorology and science and technology.

The Operational Forecast Process

Modern operational forecasting involves multiple aspects, which are shown schematically in Figure 1. It all begins with observations of the atmosphere, oceans, and land surface.

Observations are gathered from *in situ* platforms such as surface weather stations and weather balloons, or remotely sensed sensing platforms, such as Doppler and

dual-polarization radars and sophisticated satellite systems. These observations are then converted into a form that numerical computer models can use. These computer models are based upon the physical laws of atmospheric science. Atmospheric models are extremely complex, and predict variables such as temperature, moisture, and wind over the globe at time increments on the order of tens of seconds. These models have to consider factors such as snow cover, soil moisture, vegetation, sea surface temperature, solar radiation, and many others. As you can imagine, these models are computationally intensive, and continually test the limits of computer science. Figure 2 shows the growth of operational supercomputer resources since 2000 at the United States (US) National Weather Service (NWS), as measured by the number of calculations per second. A teraflop is a trillion floating-point calculations per second. Soon, more powerful petaflop computers will be used. These computers are capable of a thousand trillion calculations per second. As this computing power increases, the model representation of the atmosphere, ocean, and land surface becomes more and more realistic, resulting in improved forecasts.

Increased computing power has also allowed the advent of 'ensembles.' Ensembles are multiple model forecasts derived using slightly different initial conditions and representations of atmospheric processes. These systems account for the fact that the observations have errors, and our representation of the atmosphere also has errors. These small errors grow through the forecast period at different speeds, depending on the weather regimes. Ensembles quantify just how fast errors are growing in the forecast, and help quantify the uncertainty of the forecast. For example, each member of an ensemble provides a different possible forecast. If the differences between these possible forecasts are small, then the forecast scenario is fairly certain. However, if the members have widely different solutions, then the probability of any one scenario is small, and it is an uncertain forecast.

Output from these computer models is visualized and examined by human forecasters, who use their expert knowledge to make modifications. For example, the model may show the expected precipitation for tomorrow afternoon. The human

Figure 2 (Top) Growth of operational supercomputer resources since 2000 at the National Weather Service, as measured by the number of calculations per second (1 teraflop = 1 trillion floating-point operations per second).

forecaster considers factors such as model bias, physical realism, past verification, and consensus among various modeling systems to develop a most-likely forecast. The procedures and form in which forecasts are generated vary around the world, but it is becoming a common practice to create a database of grids of surface weather elements, which

can be graphically displayed as well as queried to create narrative text descriptions (**Figure 3**).

The final forecast information is then disseminated to a wide variety of users. Human forecasters may help interpret the impact of the weather on a particular user's need, such as whether airport runways will need to be cleared of snow, or

Figure 3 Examples of gridded and graphical forecasts from the (top) US National Weather Service, (bottom left) Australian Bureau of Meteorology, and (bottom right) United Kingdom Met Office.

more importantly whether evacuations are necessary for public safety. This decision support activity is a growing area of effort.

Modern Practice – United States

In this article, we describe the modern practice of operational meteorology using the United States as an example. This

includes public sector, military and civilian services, a vibrant private sector, and a supporting research community. The United States has one of the largest and most highly developed weather enterprises in the world. Since a number of other countries have weather enterprises somewhat similar to that of the United States, the latter provides a basic understanding of the present state of operational meteorology in the world. The US public, private, and research sectors are discussed next.

Public Sector

The public sector is shared by military and civilian efforts. The military forecasts are tailored to military needs, such as route forecasts for military ships and aircraft, and are generally not publicly available. The NWS is the public civilian effort, and is responsible for forecasting the weather, warning of weather hazards, and taking and recording observations of meteorological and hydrological conditions. This section will focus on the NWS.

The NWS accomplishes these tasks through an organizational structure comprising local forecast offices, regional offices, and national forecast centers. Working together, these offices provide the public with: (1) specific forecasts of expected weather conditions for the next 7 days, (2) general climate predictions up to 1 year in advance, (3) forecasts of potentially hazardous weather (called a 'watch'), and (4) warnings for imminent or already occurring hazardous weather.

The meteorological forecasts and services provided by the NWS can be divided into the following four basic programs:

1. *Warning Program.* Perhaps the most important function of operational meteorology is alerting society of dangerous weather. The warning program provides warnings to the public of hazardous weather and weather-related conditions. Warnings are issued for hurricanes and tropical storms, high winds, tornadoes and severe local storms, winter weather, river flooding, flash flooding, coastal flooding, high waves, and space weather anomalies, as shown in [Table 1](#). Warnings are generally issued based on

the likelihood of the event occurring and the impact the expected conditions may have.

2. *Public Weather Service Program.* This program provides the public with current weather and climate data, and forecasts ([Table 2](#)). These products also serve as the starting point for most interpretive and applied forecast services, including weather services provided by private sector meteorologists.
3. *Aviation Forecast Program.* This program provides area, route, and terminal weather information to the domestic and international aviation community to ensure safe and efficient flight operations.
4. *Marine Warning and Forecast Program.* This program provides routine forecasts, as well as watches and warnings for hazardous weather-related marine conditions.

The NWS relays weather information to the public by several methods, including the mass media, National Oceanographic and Atmospheric Administration (NOAA) Weather Radio, and other federal and international data transmission services. The media, in particular, play a critical role in disseminating weather information, including warnings of life-threatening storms.

Local weather offices

The NWS Weather Forecast Offices (WFOs) are the primary governmental providers of local weather and climate information, including warnings. There are a total of 122 WFOs, each of which has complete forecast responsibility for its particular geographic subregion during the first 7 days of the forecast. Together, these WFOs provide coverage for all of the

Table 1 Select types of hazardous weather warnings issued by National Meteorological Services and government partners

Hazard	Australia	United Kingdom	Canada	United States
Severe local storm	Severe thunderstorm		Severe thunderstorm	Severe thunderstorm
Winter weather	Severe weather	Snow Ice Cold	Tornado Snowfall Blizzard Freezing rain Windchill Cold wave	Tornado Winter storm Blizzard Ice Windchill
Flooding	Severe weather Flood	Rain Flood	Heavy rain	Flash flood Flood
Marine	Coastal waters wind Ocean wind		Marine wind	Gale Storm Hurricane force wind
Hurricane	Tropical cyclone		Hurricane	Hurricane

Table 2 Primary public forecast products issued by a US Weather Forecast Office

Product	Issuance frequency	Description
National Digital Forecast Database	At least twice daily with updates as necessary	2.5 km grids of sensible weather elements
Point-and-click forecasts (via web interface)	At least twice daily with updates as necessary	Detailed forecasts for a small area (2.5 km grid box). Typically include information on expected weather, probabilities of precipitation, the highest and lowest temperatures, and wind speed and direction. Covers periods up to 7 days.
Area forecast discussions	Four times per day	Discussion explaining the reason behind the current zone forecasts.

United States, including Puerto Rico, the U.S. Virgin Islands, and the US territories of the western Pacific.

All WFOs operate 24 h everyday of the year. Each office has a staff of ~10 forecasters, and is managed by a Meteorologist-in-Charge, a Warning Coordination Meteorologist (WCM), and a Science and Operations Officer (SOO). The WCM is responsible for developing the WFO's Warning Preparedness Program, which strives to reduce loss of life and property, and to ease the social and economic impacts of weather-related natural disasters. The WCM accomplishes this by assuring warning system efficiency, increasing public response to warnings, and providing technical help for the development of response plans by government and private institutions. The SOO serves as the primary scientific advisor to the WFO's staff, assuring the scientific integrity of all hydrometeorological products and services provided by the WFO, and is responsible for transferring new and emerging scientific technologies and techniques from the research community to the operational weather forecast and warning environment. Each office also has its own electronics and information technology staff, which is responsible for maintenance of both internal and external electronic equipment (including, among other things, WFO computer-based data acquisition and display systems, surface weather sensors, and weather radars).

Regional offices

River Forecast Centers

River Forecast Centers (RFCs) specialize in water resource information, with information on current and forecast river conditions, floods, and droughts. There are 13 RFCs in the NWS, organized by regional river systems.

Center Weather Service Units

The Center Weather Service Units (CWSUs) specialize in providing the Federal Aviation Administration Air Route Traffic Control Centers specialized weather information for regional aviation. These units promote the safe and efficient flow of aircraft within the National Airspace System. There are 21 CWSUs in the NWS.

National centers

There are nine national forecast centers forming the National Centers for Environmental Prediction (NCEP). NCEP is comprised of two core support centers:

Environmental Modeling Center – develops and improves the operational suite of model and ensemble output for weather, climate, and hydrologic forecasting.

NCEP Central Operations – runs the operational suite of model and ensemble output and disseminates this information.

The information provided by the core support centers is used by seven specialized service centers:

Aviation Weather Center – provides aviation warnings and forecasts of hazardous flight conditions at all levels within domestic and international.

Climate Prediction Center – monitors and forecasts short-term climate fluctuations and provides information on the effects climate patterns can have on the nation.

National Hurricane Center – provides forecasts of the movement and strength of tropical weather systems and issues watches and warnings for the United States and surrounding areas.

Ocean Prediction Center – issues weather warnings and forecasts out to 5 days for ocean areas poleward of 30° N in the eastern Pacific and 31° N in the western Atlantic.

Space Weather Prediction Center – provides space weather alerts and warnings for solar disturbances that can affect people and equipment working in space and on earth.

Storm Prediction Center (SPC) – provides tornado and severe weather watches for the contiguous United States along with a suite of hazardous weather forecasts.

Weather Prediction Center – provides nationwide analysis and forecast guidance products out through 7 days.

An important mission of these centers is to provide the local and regional forecast offices with guidance products and services to assist them in meeting their watch, warning, and forecast responsibilities. Additionally, some centers have watch and warning responsibility.

To illustrate the function of the national centers, and the interaction between them and the local forecast offices, we proceed with an examination of the SPC, located in Norman, Oklahoma. The SPC is responsible for issuing forecasts, watches, and watch status messages for severe thunderstorms and tornadoes across the contiguous United States. (In the United States, a severe thunderstorm is defined as one that results in one or more of the following: a tornado; straight-line winds of at least 25 m s⁻¹ (50 knots); and/or hail with a diameter of at least 1.9 cm (3/4 inches).) In addition, several times each day SPC meteorologists prepare 'convective outlooks' of expected areal coverage of nonsevere and severe thunderstorms for the next few days. A convective outlook consists of a map of the United States depicting these areas of expected thunderstorm activity (Figure 4), accompanied by text describing the underlying meteorological reasoning (see Weather Forecasting: Severe Weather Forecasting for more information about forecasting severe weather). The SPC also monitors fire weather across the country, and issues specific products for these hazards.

When it appears that severe weather will occur within the next several hours, the SPC meteorologists coordinate with WFO forecasters by an internal instant messaging service and conference calls to issue a severe thunderstorm or tornado watch for the area of concern (Figure 4). The watch is an important component of the severe weather program in the United States and places local and state government offices, as well as the public in the watch area on higher alert for the possibility of severe weather. When severe weather develops, SPC meteorologists continue to provide assistance to local offices by issuing regularly updated mesoscale discussions and watch status messages. Local offices interpret radar data, examine environmental data, and monitor storm spotter reports to issue local warnings (Figure 4). These warnings trigger sirens, mobile phone alerts, and TV crawl messages to alert the public.

Private Sector

The need for forecasts tailored to user decision making, particularly in the energy and transportation industries, has increased the role of the private sector in several industrialized countries. For example, some private sector forecasters provide

Figure 4 Example of products issued by the SPC and local WFOs for the 29–30 January 2013 outbreak. (Left) Convective outlook issued 2 days prior to the event. Areas to the right of the solid lines with arrows indicate where forecasters expect thunderstorms (severe and nonsevere) to occur during the outlook period. Areas identified as ‘SLGT’ or ‘MDT’ indicate where there is a slight and moderate risk of severe thunderstorms (those that produce either a tornado, winds $>25 \text{ m s}^{-1}$ (50 knots), or thunderstorm-generated damage, and/or hail with a diameter of at least 1.9 cm (3/4 inches).) The risk level indicates the number and/or coverage of severe thunderstorms within the identified areas. (Right) Watches (red is tornado and blue is severe thunderstorm) issued by the SPC and the hollow polygons are warnings issued by the local WFOs. Figure provided by the NOAA/NWS/Storm Prediction Center.

energy companies with detailed and specially tailored weather forecasts for particular regions to help them anticipate future energy consumption.

Many private companies use the fundamental weather forecast information from the NWS, and provide meteorological information catered to a wide range of customers in the United States, including broadcast and the Internet media, energy, and transportation companies. Private sector operational meteorologists play an important role in providing the public with reports of current and forecast weather conditions; they

also contribute significantly to the rapid and widespread dissemination of hazardous weather information from the NWS. A 2010 survey of the US public found that television, the Internet, and radio are the public’s primary sources of short-term weather information, especially during hazardous weather events (Figure 5). Commercial broadcast stations and their meteorologists work in partnership with the NWS to quickly transmit official advisories, watches, and warnings (Figure 6).

Private sector operational meteorologists are also employed by companies that provide fee-based forecasts specifically

Figure 5 Sources of weather forecasts from a national US survey of over 2000 people. The survey was conducted in 2010. Adapted from Demuth, J., Lazo, J.K., Morss, R.E., 2012. tailored to the particular needs of their customers, thus potentially adding value to the more general forecasts issued by the NWS. A citrus farmer, for example, may want to know whether temperatures will go below freezing in his field on a particular night, or a major business franchise may want to know whether the weather will affect shipments.

Other companies that employ operational meteorologists include those that provide services in the areas of air quality, climatology, training and education, forensics, research and development, instrumentation, data processing, remote sensing, and weather modification. Whatever the specific task, and whether working in the public or private sector, all operational meteorologists must have a good scientific understanding of how the atmosphere behaves, the ability to synthesize data from multiple sources quickly, and effective communication skills.

Research Sector

Operational meteorology is based on scientific understanding of the atmosphere and oceans. It is critical to infuse new research findings into applied services. Most of the applied atmospheric science research is conducted by universities and federal labs, such as the National Center for Atmospheric Research, National Severe Storms Lab, and Atlantic Oceanographic and Meteorological Laboratory. Nearly 100 colleges and universities offer Atmospheric Science or Meteorology degrees in the United States, providing a robust educational and research foundation for operational meteorology. The integration of this new science and technology into operations is discussed below in the [Integration of Science and Technology into Operations](#) section.

International Weather Services

The role of the national meteorological services in other countries is similar to that in the United States: to generate and disseminate weather observations, forecasts, and hazardous

weather advisories for the benefit of public safety and national commerce. In addition to periodic reports of weather conditions, the most common type of information provided by national meteorological services is a general weather forecast for the next several days ([Figure 3](#)). Many national meteorological centers also provide warnings for hazardous weather, similar to those issued in the United States ([Table 2](#)).

In addition to providing warnings, reports of weather conditions, and general weather forecasts, some national meteorological services also provide detailed weather information to particular industries, often those associated with transportation and energy. Frequently, these customers pay a fee to the government to receive this specifically tailored information. This fee-based model is unlike that used in the United States, where such specialized services are generally provided by individual private companies rather than government agencies.

In countries with limited resources, international efforts, such as those coordinated by the World Meteorological Organization (WMO), are necessary to help provide basic meteorological services. The WMO, a branch of the United Nations, was formed to help coordinate international cooperation among the approximately 35 regional and 190 national meteorological centers in the world. Formed in 1951, the WMO helps Member States with worldwide coordination of national meteorological activities through the establishment of cooperative agreements; the development of standards for measuring and reporting atmospheric conditions; the establishment of meteorological observation sites and training of meteorological personnel in developing countries; and the implementation of various research programs (including the World Climate Program, the Hydrology and Water Resources Program, and the Atmospheric and Environment Program).

The WMO also develops and coordinates procedures for sharing observational data and meteorological services. The Global Telecommunication System is the coordinated global system of telecommunication facilities and arrangements for the rapid collection, exchange, and distribution of meteorological and related data, forecasts, and alerts. This communication network enables real-time exchange of information, critical for forecasting and warnings of hydrometeorological hazards in accordance with established procedures. This is an especially important function, as meteorological phenomena cross geopolitical boundaries and can affect many countries at the same time. For example, when a hurricane threatens the coasts of the United States, Cuba, and Mexico, the national meteorological services in these countries work together by sharing meteorological information and resources to ensure all three countries receive adequate warning of any associated threats to life and property. The planning for this important type of international interaction is coordinated by the WMO.

Another international collaborative enterprise is the European Centre for Medium-Range Weather Forecasting (ECMWF), located in Reading, England. Formed in 1973 by a multinational convention, the ECMWF is an international organization supported by 23 European states. The objectives of the ECMWF are: (1) to develop numerical methods for medium-range (3–10 days) weather forecasting; (2) to prepare, on a regular basis, medium-range weather forecasts for distribution to the meteorological services of the Member States; (3) to conduct scientific and technical research directed to the

improvement of these forecasts; and (4) to collect and store appropriate meteorological data. Using state-of-the-art computer systems and having its own dedicated research staff, the ECMWF is the premier operational and research institutions for medium-range forecasting in the world.

Integration of Science and Technology into Operations

The evolution of operational meteorology is dependent on the capabilities of the available technology and on advances in the science of meteorology. In recent years, technological developments in four key areas have played critical roles in the advancement of operational meteorology: remote sensing of the atmosphere, computing speed and capacity, communications, and graphical display software. The first of these has resulted in the acquisition of far more comprehensive and detailed observations of the state of the atmosphere. Recent advancements in meteorological radar and satellite-borne instruments, in particular, have enabled increasingly detailed observation of the structure of the atmosphere in regions distant from the physical locations of the actual observing equipments. For example, the upgrade of the US radar network to include dual polarization now allows better detection of tornadoes, hail, heavy rain, and winter weather. With the resulting improved data coverage, numerical weather forecasts have also improved (since a prerequisite for determining the future state of the atmosphere is an accurate rendition of its present structure). These improved forecasts are related in part to the extraordinary recent increases in computing speed have also been of great significance (e.g., [Figure 2](#)). One of the primary challenges (and limitations) in numerical weather

prediction lies in trying to predict the future state of the atmosphere faster than the atmosphere itself evolves. The faster the computing devices available for carrying out the enormously voluminous and complex calculations, the more detail that can be included in the same calculation time.

Rapid increases in the quantity of observational and computer model data place increasing demand on the communication systems that carry this information to the weather enterprise. Commensurate development also becomes necessary in the equipment and techniques used to organize and display these data. Data management and display issues have been addressed through the recent development and implementation of sophisticated workstation-based meteorological graphics display software.

An example of the latter is the Advanced Weather Interactive Processing System, and its follow-on upgrade being commissioned in all forecast offices in the US NWS by 2015 ([Figure 7](#)). This system, and others like it, allows the forecaster to quickly and comprehensively examine graphical displays of both meteorological observations from multiple sources and the predicted future state of the atmosphere from numerical forecast models. The system also includes the capability for examination, generation, and dissemination of gridded, graphical, and text-based products. So, for example, a forecaster could overlay color-enhanced displays of satellite imagery, surface weather reports, weather radar data, and remotely sensed lightning strikes to quickly determine where the most severe conditions were occurring within a large thunderstorm complex, and then write and disseminate any requisite warnings.

Traditionally, the transfer of promising applied science and technology advances has been slow and challenging. This is due to the high bar operational meteorology sets; that is, the

Figure 7 A meteorologist working at an Advanced Weather Interactive Processing System workstation with a situational awareness monitor overhead at the New York City Weather Forecast Office. Adapted from NOAA.

Figure 8 (Left) Trends in NWS National Hurricane Center track errors for Atlantic Basin Tropical Storms and Hurricanes and (right) trends in NWS Weather Prediction Center rainfall skill. Improvement is noted for both phenomena. In fact, a day 3 forecast today is similar in skill to a day 1 forecast in 1990. Adapted from NOAA.

new advancement not only has to be an improvement over the current system, but also has to be efficient, sustainable, and easily adaptable to the existing operational system. To foster the transfer of promising applied science and technology advances, testbeds are playing an increasingly important role. Testbeds facilitate the testing of new advances in science and technology in a pseudo-real-time operational environment, thereby exposing the technique to the rigors of operational forecasting, including feedback from forecasters. This engagement of researchers and developers early in the testing process has resulted in an acceleration of advancements.

The combined improvements of remote sensing of the atmosphere, computing speed and capacity, communications, and graphical display software have resulted in tremendous improvement in weather forecasts. For example, a day 3 forecast of 1 inch of precipitation or the track of a tropical cyclone today is similar in skill to a day 1 forecast of these events in 1990 (Figure 8). These improvements are a testament to the power of science and technology advancements, and to the weather enterprise that has applied these advances for the benefit of society.

Emerging Trends

As in many fields, advancements in technology have provoked the question of what the role of the human should be. Traditionally, human forecasters have interpreted computer model output, and made adjustments that resulted in improved final forecasts; however, this human edge has eroded in the recent decade as models improve. Debate within the community has focused on whether the forecaster's skills are most aptly applied to the short-range forecast and warnings (first 24 h of the forecast), high-impact events at any lead time, or to the interpretation of the forecast for users.

Regardless of how involved the forecaster is in the creation of the forecast, consensus is building that human forecasters can play an important role in providing interpretive decision

support services. Users are particularly interested in how the weather will affect their critical and specific decisions. These decisions can range from whether to stage road crews for winter weather, to adjusting energy production, to considering whether mandatory evacuations are necessary. To address these societal needs, the public sector is embedding meteorologists within the Emergency Operations Centers of large cities to help the emergency management community understand the weather forecast and the impacts relative to their decisions. An example from the private sector is the close consultation with energy providers on the ramp-up and ramp-down of energy production to meet demand.

As meteorologists provide these interpretive services, new challenges are arising. For example, what is the best way to communicate uncertain weather information? What forms of communication (for example, verbal or graphical) are most effective in fostering understanding? How can one motivate individuals to evacuate in life-threatening weather situations? Operational meteorologists are partnering with social scientists to help answer these types of questions.

A key area of focus has been on the use of weather information to minimize cost and risk. Although in its infancy, cost-loss models are being used in various industries. Consider the example of resource protection, where a citrus farmer has to decide whether to take mitigating action to save the crop (Figure 9). In this case, there is a cost to the mitigating action, but also a potential large loss if mitigating action is not taken and a damaging freeze occurs. The farmer needs to know at what risk of a damaging hard freeze the benefit of taking mitigating action outweighs the cost. Cost-loss models consider the probabilities of a loss (damaging hard freeze), and the cost of taking the mitigating action (such as water, fuel, and overtime). In other words, they help determine the user's risk tolerance. If the risk of an event is greater than this risk tolerance, mitigating action should be taken. A complementary example of resource acquisition is shown in Figure 9. These cost-loss models may not take into account other social factors, such as social credibility, local politics, and policies, and so may not be

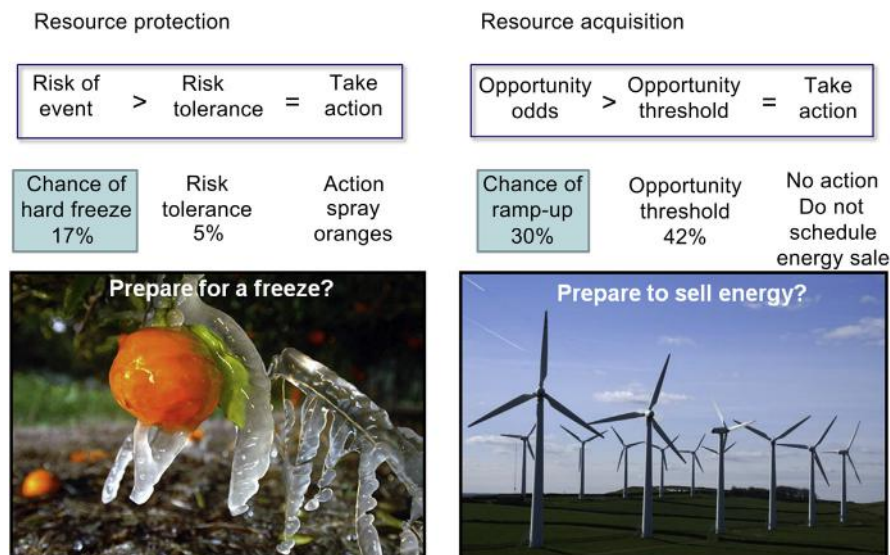

Figure 9 Examples of using cost-loss concepts for resource protection (left) and resource acquisition (right). Adapted from NOAA.

completely calibrated, but cost-loss models are an emerging tool for operational meteorologists conducting decision support.

Additionally, as weather forecasts improve, there are emerging areas of application including air quality, water quality, ecosystem health, and human health. For example, air quality is sensitive to temperature, humidity, atmospheric stability, sunshine, and wind. Detailed forecasts of these parameters are critical to anticipate harmful air quality days. Similarly, heavy rainfall can wash pollutants and fertilizers into watersheds, disrupting the natural ecosystem. The weather also impacts human health. For example, wet, warm conditions with warm nights can increase the mosquito population, leading to increased spread of disease.

Despite the enormous advances made in operational weather forecasting during the twentieth century, theoretical predictability studies suggest significant further improvement remains possible. As this evolution continues, operational meteorology will remain the bridge between our scientific understanding of how the atmosphere behaves and the application of this knowledge for the safety and benefit of society.

This article is a revision of the previous edition article by M Hoerling and A Kumar, volume 6, pp 2562–2567, © 2003, Elsevier Ltd.

Synopsis

This article presents a brief review of the current state of knowledge and capability in seasonal and interannual prediction. The review covers several relevant major issues, including (1) the definition and scientific basis of seasonal and interannual prediction; (2) the nonlinear local Lyapunov exponent predictability theory and its application in quantifying the seasonal predictability limit; (3) current approaches to seasonal and interannual predictions; and (4) current practice in seasonal and interannual predictions. Within this context, some of the major challenges remaining in interannual climate prediction are addressed.

Introduction

Climate predictions are inherently probabilistic statements about the future climate conditions on timescales ranging from seasons to decades or longer, and on spatial scales ranging from local to regional and global. Specifically, predictions of seasonal and interannual weather (i.e., short-term climate) are predictions of the departures from the average (normal) climate for upcoming seasons, and these are distinct from short-range weather predictions that attempt to deterministically forecast day-to-day weather behavior. Such predictions may provide some statistics on the seasonal or annual mean anomaly together with a measure of its probability of occurrence, and such information is useful for governmental, nongovernmental, and private agencies in making long-term decisions and planning in various fields (e.g., farming, early warning of potential hazards, drought mitigation, disaster prevention, insurance policy, and other economic activities). In the past two decades, there has been substantial progress in seasonal predictions, and now many operational and research centers around the world routinely make such predictions. The success of seasonal predictions has arisen from an improved understanding of the sources and limits of seasonal predictability as well as advances in climate models.

The sources of predictability vary with the timescale, influenced by the timescales of the predictands (i.e., the variables to be predicted). Slowly varying boundary conditions, such as sea surface temperatures (SSTs), sea ice, soil moisture, and snow cover at the surface, are common sources of predictability on seasonal and interannual timescales. One of the most important sources of seasonal and interannual climate predictability is the El Niño–Southern Oscillation (ENSO) phenomenon, which is the dominant mode of variability in the tropical Pacific at interannual timescales and that has a widespread effect on the global climate system. Recent research has indicated that the influence of the stratosphere on the troposphere is also an important source of seasonal predictability. Despite these sources, the utility of seasonal and interannual climate prediction is limited by errors in initial and boundary conditions, and by deficiencies in prediction models. The time-averaged seasonal anomalies in current prediction models can only be accurately predicted for a lead time of a few

months, thereby indicating that the predictability of such anomalies is inherently limited. It is useful to know the limits of seasonal and interannual predictability, as such information could be used to guide improvements in prediction models.

Various methods have been proposed to estimate seasonal and interannual predictability. Most of these methods assess the relative strength of the potentially predictable ‘climate signal’ due to the boundary forcings and of the unpredictable ‘climate noise’ due to intrinsic random variations, or the ‘signal-to-noise’ (S/N) ratio. However, the method employed to calculate the S/N ratio provides only a qualitative measure of seasonal and interannual predictability, such as identifying regions as being either predictable or unpredictable, but without quantifying the limits of predictability.

Recently, nonlinear methods have been introduced to quantitatively measure seasonal and interannual predictability. For example, the nonlinear local Lyapunov exponent (NLLE), which is a nonlinear extension of the traditional Lyapunov exponent concept, can quantitatively determine the limit of seasonal and interannual predictability by exploring the divergence evolution of the distance between initially local dynamical analogs (LDAs) from the observational time series. Using the NLLE method, it is possible to determine how far ahead we can predict the time-averaged seasonal anomalies in different regions. In addition to the NLLE, other nonlinear methods, such as the condition nonlinear optimal perturbation, have been introduced and applied to analyses of ENSO prediction and predictability.

Basic approaches to seasonal to interannual predictions include empirical approaches trained on observational data, dynamical approaches using general circulation models (GCMs), and combinations of these approaches. Regardless of the procedure, these predictions often show relatively low skill due to the influences of random weather fluctuations and other sources of unpredictability, particularly in areas away from the tropics. Given this limited predictability, it is more appropriate to make probabilistic seasonal and interannual predictions rather than deterministic predictions, since a probabilistic prediction yields estimates of the probability that the seasonal or annual mean temperature and precipitation will be above, near, or below normal, and provides quantitative information regarding prediction uncertainty.

Seasonal prediction products are now available from World Meteorological Organization (WMO)-designated Global Producing Centres (GPCs) of Long-Range Forecasts and are produced on multiple spatial scales by using GCMs to serve a wide range of users for various purposes. However, validation of these products is limited by the predictability of predictands. Empirical approaches based on an understanding of physical mechanisms on how predictors impact predictands are also sometimes employed to provide more skillful seasonal forecasts. Interannual prediction products currently have relatively low skill levels and are not available at most forecasting centers; consequently, there is a need for vast improvements in dynamical or empirical models for interannual predictions.

Quantifying Seasonal and Interannual Predictability

Previously, seasonal and interannual predictability has mainly been estimated using the S/N ratio method. The 'climate signal' arises from the slowly varying boundary forcings and represents the potentially predictable component of seasonal variability. The natural variability, or 'climate noise,' due to internal dynamics, represents the unpredictable component of seasonal variability. Under the assumption that the nonlinear interactions between signal and noise are small, evaluating the ratio of their variances will provide a qualitative assessment of the seasonal predictability. However, this method has several limitations. First, the climate signal and noise are not entirely independent or linearly separable, and their nonlinear interactions are sometimes strong and might make an important contribution to predictability. Second, the natural variability is not completely unpredictable. The internal dynamics and persistence of the atmosphere could also provide some predictability. Finally, the S/N ratio method provides only a qualitative (not quantitative) measure of seasonal and interannual predictability. In fact, we are sometimes more concerned with how far ahead we can predict the time-averaged seasonal anomalies. Here we quantitatively estimate seasonal and interannual predictability, using the NLE method that has recently been introduced to quantitatively measure the predictability of dynamical systems.

For any dynamical system, the NLE, λ , is defined as:

$$\lambda[x(t_0), \delta(t_0), \tau] = \frac{1}{\tau} \ln \frac{\|\delta(t_0 + \tau)\|}{\|\delta(t_0)\|}, \quad [1]$$

where $x(t_0)$ denotes an initial state in phase space, $\delta(t_0)$ the initial error, t_0 initial time, τ evolution time, and $\delta(t_0 + \tau)$ the evolution error. The ensemble mean NLE over the global attractor of the dynamical system is given by

$$\begin{aligned} \bar{\lambda}[\delta(t_0), \tau] &= \int_{\Omega} \lambda[x(t_0), \delta(t_0), \tau] d\Omega \\ &= \langle \lambda[x(t_0), \delta(t_0), \tau] \rangle_N, \quad (N \rightarrow \infty) \end{aligned} \quad [2]$$

where Ω represents the domain of the global attractor of the system and $\langle \lambda[x(t_0), \delta(t_0), \tau] \rangle_N$ denotes the ensemble average of samples of sufficiently large size N ($N \rightarrow \infty$). The ensemble mean NLE reflects the global evolution of mean error growth over an attractor and can measure global mean predictability.

For nonlinear dynamical systems, we can directly calculate the mean NLE via the numerical integration of their error

evolution equations. In addition, if large amounts of observational or experimental data are available for dynamical systems, we can estimate the mean NLE by making use of these data when the evolution equations of the systems are either unknown or incomplete. The general idea of the algorithm to estimate the mean NLE based on observational data is to find LDAs of evolution patterns from observational time series. The LDA is based on the initial information and evolution information at two different time points in the time series. Considering that the initial information of chaotic systems will gradually decay at an exponential rate, the error within the evolution time interval, which is defined as the time at which autocorrelations of observational time series drop to below the 95% significance level, is multiplied at each step by a weighting coefficient that decreases at an exponential rate with time. The exponential rate can be estimated from autocorrelations of observational time series. For observational time series at different grid points, the evolution time interval and exponentially decreasing weighting coefficients are taken as their average over all grid points. The mean NLE is then estimated by calculating the mean exponential divergence rate of the LDAs, and the mean error growth is obtained by calculating the mean root-mean-square error (RMSE) for all LDAs. The mean RMSE is chosen as a measure of error because it bridges a close relationship between the error saturation value and the standard deviation (SD) of the observational time series, as will be shown later.

The mean error growth obtained by calculating the mean RMSE between LDAs initially increases quickly then slows down and finally reaches a saturation value (Figure 1). According to the dynamical systems theory, the error saturation value represents the average distance between two randomly chosen points over an attractor, which is also referred to as the attractor radius (AR). The AR is equal to $\sqrt{2}$ times the SD of the observational time series. The saturation level of error growth implies that almost all information on initial states is lost and the prediction becomes meaningless. The potential predictability limit is then determined as the time at which the mean error reaches the AR, while the practical predictability limit is determined as the time at which the mean error reaches the SD (Figure 1). The potential predictability limit may only be

Figure 1 Schematic illustration of the determination of practical and potential predictability limits via the mean error growth as a function of time, obtained by calculating the mean root-mean-square error (RMSE) between local dynamical analogs (LDAs). The upper and lower red dashed lines represent the amplitudes of attractor radius (AR) and standard deviation (SD) of observational time series, respectively.

attained when the models are able to realistically predict dynamical systems with very small initial and model errors. The practical predictability limit may be attainable through recently achievable enhancements to existing models of nonlinear dynamical systems. The error growth will enter a strong nonlinear phase with a steadily decreasing growth rate when the magnitude of the mean error exceeds the SD, which is always poorly represented in models of nonlinear dynamical systems. Therefore, modelers undoubtedly face big challenges in improving their models to attain the potential predictability limit.

Predictability is generally dependent on time and space and is controlled by multiple forcing factors, which leads to considerable difficulty in understanding the sources of predictability. Therefore, it is necessary to separately investigate the effect of each forcing factor on predictability. Conditional predictability can be considered as an estimate of the predictability of a certain variable of dynamical systems due to forcing by, or explained by, one or more factors. For example, ENSO is one of the primary boundary forcings for the monthly and seasonal predictability of the atmosphere. The conditional NLE is introduced to study the conditional predictability of the atmosphere associated with ENSO. Let $\mathbf{x}$ and $\mathbf{y}$ be one-dimensional or multi-dimensional vectors of dynamical systems, and assume that the vector $\mathbf{y}$ acts as an external forcing factor for the vector $\mathbf{x}$. To investigate the effect of $\mathbf{y}$ on the predictability of $\mathbf{x}$, the conditional NLE $\lambda_{\mathbf{x}|\mathbf{y}}$ of $\mathbf{x}$ given $\mathbf{y}$ is defined as:

$$\lambda_{\mathbf{x}|\mathbf{y}}[\mathbf{x}_{\mathbf{y}}(t_0), \delta_{\mathbf{x}|\mathbf{y}}(t_0), \tau] = \frac{1}{\tau} \ln \frac{\|\delta_{\mathbf{x}|\mathbf{y}}(t_0 + \tau)\|}{\|\delta_{\mathbf{x}|\mathbf{y}}(t_0)\|}, \quad [3]$$

where $\mathbf{x}_{\mathbf{y}}(t_0)$ denotes the initial state of $\mathbf{x}$ given $\mathbf{y}$, $\delta_{\mathbf{x}|\mathbf{y}}(t_0)$ the initial error, t_0 initial time, τ the evolution time, and $\delta_{\mathbf{x}|\mathbf{y}}(t_0 + \tau)$ denotes the nonlinear error of $\mathbf{x}$ at the time $t_0 + \tau$ under the influence of $\mathbf{y}$. For observational time series of $\mathbf{x}$ and $\mathbf{y}$, linear regression can be used first to extract the components of $\mathbf{x}$ explained by $\mathbf{y}$. Through searching the LDAs between the regressed time series and the original time series of $\mathbf{x}$, the conditional NLE is then estimated by calculating the mean exponential divergence rate of initially analogous points.

The NLE method may be applied to quantitatively estimate the predictability limit of different atmospheric, oceanic, or other climate variables at different timescales. Figure 2 shows the spatial distribution of the annual mean practical predictability limit of daily 500-hPa geopotential height (GHT), as obtained using the NLE method. The practical predictability limit of the National Centers for Environmental Prediction (NCEP)/National Center for Atmospheric Research (NCAR) reanalysis data appears to have a zonal distribution, with a maximum of 14–15 days over the tropics and Antarctic, followed by 13–14 days over the Arctic, 8–13 days over mid-high latitudes in the Northern Hemisphere (NH), and the lowest limit of 7–12 days over midlatitudes in the Southern Hemisphere (SH). The existence of storm tracks and strong baroclinicity over the midlatitudes may explain the relatively low predictability limit in these latitudes. In contrast, the practical predictability limit of the CFSv2 forecasts has a very different distribution, with a maximum limit of 7–9 days over the NH mid-high latitudes, followed by nearly 7 days over the SH mid-high latitudes, and the lowest limit of 3–6 days over the tropics. The results suggest that there is considerable potential for numerical models to increase their predictability through model improvement, especially in the tropics.

Figure 3 shows the spatial distributions of annual mean limits of practical and potential predictability of monthly and seasonal 500-hPa GHT and monthly mean SST. The practical predictability limits of monthly and seasonal mean 500-hPa GHT both appear to be highest over the tropics between 15° S–15° N (a maximum over the Western Pacific warm pool), with values greater than 4 months and 2 seasons, respectively. Correspondingly, the practical predictability limit of monthly mean SST is also the greatest in the tropics, including the tropical Central-Eastern Pacific, and tropical Indian and Atlantic Oceans, where values exceed 8 months (the maximum exceeds 10 months over the tropical Central-Eastern Pacific). However, relatively lower predictability of SST is observed over the Western Pacific warm pool. In comparison, the distributions of the practical predictability limit for monthly mean 500-hPa GHT in the tropics are more uniform than those for monthly mean SST, possibly because the entire tropical atmosphere may respond quickly to SST forcing in the tropical

Figure 2 Spatial distribution of the annual mean practical predictability limit (days) of daily 500-hPa geopotential height (GHT), obtained using the NLE method. (a) The NCEP/NCAR reanalysis data (1948–2010). Daily data are obtained as a 1-day running mean of the 6-hourly daily 500-hPa GHT. (b) The NCEP CFSv2 daily forecasts. The predictability in the CFSv2 is estimated by verifying the 45-day retrospective forecasts of CFSv2 against the NCEP/NCAR reanalysis data for the period 1999–2000. (c) The zonal mean profiles of practical predictability limit. The black and blue lines are for the reanalysis and model, respectively.

Figure 3 Spatial distribution of the annual mean practical (left panel) and potential (right panel) predictability limits of 500-hPa GHT from the NCEP/NCAR reanalysis (1948–2010) and SST from the HadISST (1900–99) at monthly and seasonal scales and their corresponding zonal mean profiles (middle panel), obtained using the NLE method. Upper, middle, and lower panels are for monthly, seasonal, and monthly scales, respectively, and units in the panels are month, season and month, respectively. The black and blue lines in the middle panels of zonal mean profile are the practical and potential predictability limits, respectively. Monthly (seasonal) data of 500-hPa GHT are obtained as 30-day (90-day) running means of the 6-hourly 500-hPa GHT. Monthly mean SST data are used directly.

Central–Eastern Pacific, and tropical Indian and Atlantic Oceans. The practical predictability limits for 500-hPa GHT and SST gradually decrease from the tropics to mid–high latitudes. At mid–high latitudes, the practical predictability limits of monthly and seasonal mean 500-hPa GHT are only 2 months and 1.5 seasons, respectively, while the limit for monthly mean SST is mostly below 8 months.

Compared with the practical predictability limits, the potential predictability limits of monthly and seasonal mean 500-hPa GHT and monthly mean SST have similar distributions but with much higher values over the tropics. The higher potential predictability for both the atmosphere and SST in the tropics may arise from the strong ocean–atmosphere feedback and slowly varying SST forcing, which can result in a small error growth rate even after a few months.

As mentioned above, ENSO is an important source of atmospheric predictability on seasonal and interannual time-scales. Figure 4 shows the distributions of annual mean limits of practical and potential predictability for monthly 500-hPa GHT explained by the ENSO index, obtained using the

conditional NLE. Both the ENSO-related practical and potential predictability limits are largest in the tropics and exceed 2.5 months. In particular, the two regions with the highest predictability limits are the Central–Eastern equatorial Pacific and Western Pacific warm pool, where the two corresponding poles of the Southern Oscillation are located. There, over 50% of the monthly atmospheric predictability is related to monthly variations in tropical Pacific SST. In contrast, ENSO makes little contribution to predictability outside the tropics, other than along the two great circle routes spanning the Pacific–North American (PNA) and Pacific–South American (PSA) teleconnection patterns, where about 1 month of practical predictability and 2 months of potential predictability are related to ENSO. The stronger response to ENSO of the PSA pattern than the PNA pattern results in a higher conditional predictability in the PSA region than in the PNA region. It is these two teleconnection patterns, constructing a remote relationship between mid–high latitude atmospheric circulation and tropical ENSO-related SST, that provide useful information for seasonal and interannual predictions over North and South America.

Figure 4 Spatial distributions of the annual mean practical (a) and potential (b) predictability limits (months) of monthly 500-hPa GHT explained by the ENSO component, obtained using the conditional NLLE method.

Approaches to Seasonal and Interannual Predictions

Currently, seasonal to interannual climate predictions are based on dynamical and empirical approaches as well as combinations of such approaches. In the past, statistical approaches were most commonly used for climate predictions. However, with the rapid development of computing technologies and great improvements in model parameterization, dynamical approaches have become effective tools for climate predictions. To date, operational climate prediction products from WMO GPCs of Long-Range Forecasts (e.g., European Centre for Medium-Range Weather Forecasts (ECMWF) and NCEP's Climate Prediction Center (CPC)) are based on dynamical approaches, which are likely to be the main method of climate prediction in the coming decades.

Dynamical seasonal prediction approaches utilize GCMs, including atmospheric GCMs, coupled ocean–atmosphere GCMs, or more complex coupled climate system models that consider the roles of atmosphere, ocean, land surface, and sea ice. External boundary forcing conditions and the extent to which the boundary conditions can be predicted are important factors for successful climate predictions by dynamical models. SSTs, especially tropical Pacific SSTs, are one of the most important boundary conditions for atmospheric models, since the predictability of SSTs in the tropics is higher than that in other regions, as mentioned before. The highly predictable SSTs in the tropics contribute to the high predictability limit of the overlying atmosphere through strong air–sea interaction, which is essential for predicting the ENSO cycle. Another factor that influences model predictions is uncertainties in the initial conditions. Since the climate system is strongly nonlinear, regional or global climate systems may contain multiple equilibria coexisting under the same external forcing, and the final equilibrium state depends on the initial conditions. Consequently, climate prediction models must consider errors in the initial and boundary conditions in coupled GCMs. In addition, the reference climatology used for the definition of climate anomalies, which is generally the most recent 30-year average, is also an impact factor that influences predictions. This factor is also relevant to empirical approaches to climate prediction.

Dynamical models used for seasonal predictions can be classified as simple models, intermediate-complexity coupled models, hybrid coupled models, and coupled GCMs,

depending on the degree of complexity of the models. Simple dynamical models are the simplest of these models and are useful tools for studies of climate dynamics. Such models have the potential to yield skillful predictions, as the validity of the prediction is not entirely dependent on the degree of complexity of the models. To reduce the uncertainty associated with errors in the initial conditions, ensemble prediction techniques, which conduct multiple numerical predictions using slightly different initial conditions to attempt to generate a representative prediction, are employed. To reduce uncertainties associated with the physical parameterization scheme, which differs among models, multimodel ensemble (MME) techniques are employed and have proven to be extremely effective. MME approaches are the best currently available for quantifying and resolving uncertainties, and have proven to produce better predictions than any single model alone.

Dynamical approaches have a number of advantages. They are not only unconstrained by linear relationships between the predictors and predictands of interest, but can be used to predict unprecedented conditions, especially for a nonstationary climate. In addition, dynamical approaches can help us to understand the physical mechanisms that underlie the statistical relationships established by purely empirical approaches. However, dynamical approaches are limited by intensive computing requirements and large model biases in physical parameterizations, which limit the seasonal forecast skill. Moreover, dynamical approaches also suffer from errors introduced because of imperfections in the model formulation as well as the numerical methods to approximately solve the evolution equations of the dynamical system. Empirical approaches are sometimes used as a supplement to dynamical approaches.

Empirical approaches, which are the simplest way to make climate predictions, fall into two categories: purely statistical relations between possible predictors and predictands of interest, and physically based linkages between predictors and predictands based on an understanding of the underlying physical mechanism. The latter methods have a physical basis and generally show better forecasting performance. Many statistical methodologies, including linear and nonlinear methods, have been applied to identify physical links between predictors and predictands. A climate variable is usually characterized by multitimescale variabilities that are controlled or driven by different climate factors at different timescales.

Consequently, a timescale decomposition (TSD) downscaling approach is used for statistical downscaling, which estimates how local or regional climatic variables (e.g., the temperature, precipitation, and wind speed at a particular site or over a region) are affected by large-scale climatic conditions (e.g., atmospheric surface pressure, GHT, SST, ENSO), in order to separate predictands with distinct multitimescale features into different timescale components that are associated with different predictors. The TSD model makes use of different downscaling models that correspond to different timescale variability linked to various mechanisms. The TSD model has been successfully applied to seasonal predictions of summer (July–August) rainfall over North China.

There are some quite successful cases of empirical predictions. For example, the connections the East Asian summer monsoon (EASM) with ENSO and spring (April–May) North Atlantic Oscillation (NAO) have been established. The EASM variability is strongly linked to not only the winter (December–January–February (DJF)) ENSO but also the spring NAO. NAO anomalies in spring can trigger a tripole SST pattern in the North Atlantic that persists into the subsequent summer. The tripole SST pattern in summer impacts EASM through two pathways: (1) it can excite an Atlantic–Eurasian (AEA) teleconnection pattern over mid–high latitudes, which may strengthen (or weaken) the East Asian subtropical front (Meiyu–Baiu–Changma), leading to a strong (or weak) EASM; and (2) the tropical Atlantic can strongly modulate the western subtropical high, which is an important linkage between the EASM and the DJF ENSO. Based on the underlying physical mechanism, an empirical NAO–ENSO-based seasonal prediction model of the EASM has been constructed and has been shown to produce skillful seasonal predictions of the EASM and summer rainfall over the Yangtze River valley. Another example of a successful empirical prediction is the connection between the spring (March–April–May) precipitation in the Nordeste region of Brazil and tropical Atlantic SST in the months before the rainy season.

Empirical approaches to seasonal predictions have a number of advantages. Compared with dynamical approaches, empirical approaches are easy to apply, as they are much less computationally expensive. In addition, they are unaffected by model errors in parameterizations. However, there are some limitations in empirical approaches. The relationships between predictors and predictands established by such approaches are usually linear, which ignores the nonlinear processes between them. Although some nonlinear statistical methods can be used, they are prone to overfitting noise. Furthermore, empirical approaches might have difficulty predicting abrupt changes in climate, and they are limited by the length of time series of observed data. Nonetheless, recent investigations show that the reliability of physically based empirical approaches has been enhanced by an improved understanding of the physical and dynamical processes that underlie the way in which forcing (predictors) impacts on predictands.

Climate predictions at an interannual timescale have received increasing attention in recent years. Such predictions bridge the gap between seasonal and decadal predictions, and have the potential to provide information on the climate conditions and climate risks in upcoming years, which would be valuable for decision making in various sectors such as

agriculture, energy, economics, and infrastructure. However, in contrast to seasonal predictions, interannual climate predictions are at an early stage of development, and the effective sources and limits of interannual predictability remain unclear. As the strongest signal of interannual climate variability, ENSO can be predicted only at lead times of up to 1 year, beyond which predictions become meaningless. In addition, many potential sources of predictability are not considered in current models and approaches. Thus, the refinement of interannual predictions faces great challenges. In the context of current efforts to improve interannual climate predictions, it is necessary to examine the sources and limits of interannual predictability. Much work is required to improve the level of prediction skill on such a timescale.

Current Practice in Seasonal and Interannual Predictions

Due to the importance of climate predictions in long-term decision making, and the possibility that such predictions can provide an early warning of potential future hazards, climate prediction products have become the focus of increasing public interest. Climate predictions can be produced at global, regional, or local scales to serve users with different purposes; however, their use must take into account the predictability limits of the predictands. That is, predictions that are made beyond the predictability limits of the predictands have no practical value.

There are several centers currently generating global climate predictions, and these include the WMO GPCs of Long-Range Forecasts; e.g., CPC/NCEP/National Oceanic and Atmospheric Administration (NOAA), ECMWF, the Australian Bureau of Meteorology, the Beijing Climate Center of China Meteorological Administration, and the UK Met Office. Regional climate prediction products are produced by the WMO Regional Climate Centers and also the Regional Climate Outlook Forums with the aim of delivering better climate services and improving the ability to meet national climate information needs related to reducing climate-related risks and supporting sustainable development. In addition, many nations generate national climate prediction products at the seasonal scale, which are the responsibility of the national meteorological and hydrological services.

Seasonal prediction products from the CPC and ECMWF are generated using their own forecasting systems. The CPC uses the so-called US National MME (NMME), which is an experimental multimodel seasonal forecasting system comprising coupled models from US modeling centers, including NOAA/NCEP, NOAA/Geophysical Fluid Dynamics Laboratory (GFDL), International Research Institute for Climate and Society (IRI), NCAR, National Aeronautics and Space Administration (NASA), and Canada's Canadian Meteorological Center (CMC). The ECMWF employs the European multimodel seasonal to interannual prediction (EUROSIP) system, which is based on coupled models from the ECMWF, UK Met Office, Météo-France, and NCEP. The CPC seasonal predictions are issued with probabilities calibrated against past cases by statistical forecast tools, but the ECMWF predictions are not calibrated in this way, primarily because of the limited number of past predictions.

Figure 5 Examples of MME tercile categorical seasonal prediction. (a) Global seasonal mean 2 m temperature. With permission from CPC NMME. (b) As for (a) but for precipitation. (c) As for (a) but for the tropics. With permission from ECMWF EUROSIP. (d) As for (c) but for precipitation. With permission from ECMWF EUROSIP. These prediction products are based on a start date of July 2013 and show the 3-month outlooks (August–September–October (ASO) 2013) for a lead time of 1 month. The expected changes in probabilities (%) of three categories are shown: above normal, below normal, and neutral for CPC, and below lower-tercile, above upper-tercile, and between the lower and upper terciles for ECMWF.

Figure 5 shows some examples of MME tercile categorical seasonal predictions by the CPC and ECMWF for 2 m temperature and precipitation. The predictions from the CPC were produced at the given lead times from 1 to 5 months, but for the ECMWF ranged from 1 to 3 months. The CPC produces global seasonal predictions (predictions for 2 m temperature are available over the land), while the ECMWF predictions only cover the tropics (possibly due to the higher predictability in the tropics), implying a difference in seasonal prediction products between the ECMWF and CPC. For this case, the two centers show a similar seasonal probabilistic prediction of the mean 2 m temperature in the tropics over land; i.e., a warming trend in Africa, East Asia, and the Maritime continent, and a cooling trend in South America. The seasonal precipitation predictions over the tropics from the two centers are also similar, but for the region from West Africa to Arabia, there is a wetting trend in the CPC prediction, but a neutral condition in the ECMWF prediction.

Verification of these predictions is required to provide an indication for users of the extent to which the predictions are credible. Figure 6 is an example of the verification of the seasonal precipitation predictions for the continental United States at a lead time of 0.5 months using the Heidke Skill Score from the CPC. A score of 100 denotes a perfect prediction,

a score of -50 indicates a completely incorrect prediction, and 0 denotes a random prediction. As shown in Figure 6(a), although there are a few cases with higher scores, the mean value of all manuals is less than 5.0, indicating the low skill of the seasonal prediction. There are seasonal fluctuations in this verification; i.e., a higher score in winter–spring and a lower score in summer–autumn. Seasonal variations in the predictability of seasonal precipitation may account for this, and the more deep-rooted causes of such fluctuations are related to seasonal changes in the predictability of predictors. Furthermore, the skill score shows a distinct spatial distribution (Figure 6(b) and 6(c)); i.e., higher scores in southern continental United States, and lower scores in northern continental United States.

ENSO is one of the key prediction objectives in operational seasonal predictions. Figure 7 shows two examples of the seasonal prediction products of Niño3.4 SSTs (5° N– 5° S, 120° – 170° W) from the ECMWF EUROSIP and CPC NMME. The EUROSIP and NMME produce predictions for up to 6 and 8 months ahead, respectively. For the predictions at the start time of September 2012, the two predictions have large uncertainties, and their MMEs have larger prediction errors, showing the low skill of the predictions for this case. The observational Niño3.4 index reaches a peak in August 2012, and enters its

Figure 6 Example of verification of seasonal precipitation prediction for the continental United States at a lead time of 0.5 months using the Heidke Skill Score (ranging from -50 to 100) from the CPC. (a) Seasonal precipitation Heidke Skill Score for all categories from January 1995 to March 2013. The blue dashed line is the average skill score. (b) and (c) are the distributions of the skill score of all manuals, and the November–December–January (NDJ) manuals, respectively.

negative phase in September 2012. However, the two predictions did not capture this phase transition. This example shows that against a background of ongoing climate change, the complexity of the climate system may increase, which will make it increasingly difficult to predict ENSO, even though it has

a higher predictability. The predictions at the start time of July 2013 from the two systems suggest that the Niño3.4 index may go to a positive phase during the next half year.

Physically based empirical approaches are often used to develop seasonal prediction products. For example, the TSD

Figure 7 Examples of seasonal forecast of Niño3.4 SSTs (5°N – 5°S , 120° – 170°W). (a, c) with permission from ECWMF EUROSIP and NMME (b, d) with permission from CPC NMME. (a) and (b) indicate the predictions made at a start time of September 2012. (c) and (d) denote the predictions made at a start time of July 2013. Predicted monthly mean anomalies from each individual ensemble member of EUROSIP (NMME) are relative to the NCEP Olv2 1981–2010 climatology (OISST, 1982–2010 climatology) and shown as red dotted lines (colored lines). The observations are represented by the thick dashed blue lines in (a) and (c), and black solid lines in (b) and (d). The dashed black lines in (b) and (d) indicate the MMEs of all members.

downscaling model is used in the seasonal prediction of summer (July–August) rainfall over North China. This model of interannual summer rainfall variability over North China is linked to the June ENSO and June AEA teleconnection, while that for interdecadal summer rainfall variability over North China is related to the decadal variability of sea level pressure over the southwest Indian Ocean. Taking the downscaled interannual and interdecadal components together, the downscaled total rainfall was obtained. The independent validation shows a better prediction skill for the TSD approach. The TSD model was used by the National Climate Center of the CMA to make seasonal predictions of summer rainfall over North China in 2010, 2011, and 2012, and these predictions were consistent with observations. The summer rainfall anomaly for 2013 over North China by the TSD model was above normal (not shown).

Further successful examples of empirical predictions are the empirical NAO–ENSO-based seasonal prediction models of the EASM index (EASMI) and summer precipitation (RI_{YR}) over the middle and lower reaches of the Yangtze River valley, as mentioned above. These empirical seasonal prediction models

were derived using a linear regression method for the period 1979–2006, as follows:

$$\begin{aligned} \text{EASMI} = & 11.56 + 0.60 \cdot \text{NAOI} + 0.22 \cdot \text{ENSO}_{\text{develop}} \\ & - 0.43 \cdot \text{ENSO}_{\text{decay}}, \end{aligned} \quad [4]$$

$$\begin{aligned} RI_{YR} = & -5.92 - 0.41 \cdot \text{NAOI} - 0.04 \cdot \text{ENSO}_{\text{develop}} \\ & + 0.22 \cdot \text{ENSO}_{\text{decay}}. \end{aligned} \quad [5]$$

Here, NAOI denotes the mean NAO index value for April–May, $\text{ENSO}_{\text{develop}}$ the Niño3.4 index difference between April–May and February–March, and $\text{ENSO}_{\text{decay}}$ the Niño3.4 index for the preceding winter (DJF). The seasonal predictions of the EASMI and RI_{YR} generated using these models (Figure 8) show that the performance of seasonal predictions for both EASMI and RI_{YR} between 2007 and 2012 is good, implying that the empirical models are effective tools for the seasonal prediction of EASM. The predictions for 2013 by the models show a somewhat stronger EASM, and reduced summer precipitation over the middle and lower reaches of the Yangtze River valley.

Figure 8 Example of seasonal prediction of the EASMI (a) and summer (JJA) precipitation $R1YR$ over the middle and lower reaches of the Yangtze River valley (b) using the NAO–ENSO-based seasonal prediction model. All values are normalized. The observations are indicated by dashed lines, and the model results by solid lines. The model fit period is 1979–2006, and the prediction period is 2006–13.

Interannual predictions are extremely difficult and relevant research in this area remains limited; consequently, very few interannual prediction products are currently available. Therefore, additional research is required to develop such products in the future.

Synopsis

Severe weather is any type of violent or extreme weather event that represents a hazard to public safety and welfare, including tornadoes, damaging windstorms, flash floods, lightning, and hailstorms. The societal costs of severe weather events are very high, involving injuries, lost lives, and property damage. Accurate severe weather forecasts help reduce the loss of life and mitigate economic loss. The severe weather forecasting process requires knowledge of climatology and incorporates the techniques of pattern recognition and parameter evaluation as applied to both observations and numerical weather prediction model forecasts.

Introduction

Severe weather is any type of violent or extreme weather event that represents a hazard to public safety and welfare. In the United States, the country that arguably has the largest severe weather threat, the term severe weather is applied only to those events associated with severe local thunderstorms, such as tornadoes, hail, lightning, and damaging surface winds. In other countries, it is more common to include hurricanes, flash flooding, fire weather, or winter storms in the definition of severe weather, since these weather-related events mostly affect public welfare. Hurricanes, in particular, are a significant weather hazard, but owing to their longer lifetimes and limited geographic region of influence, they are not considered here. The specific events that are covered under the umbrella of severe weather are not as important as the recognition that weather events influence our daily lives and can be both a blessing and a hazard.

The human and economic costs of severe weather events can be very high, involving injuries, lost lives, and significant property damage. Accurate severe weather forecasts help reduce the loss of life and mitigate economic loss by encouraging people to seek shelter or limit their exposure to the threat, by encouraging businesses to alter their plans, and by helping governments to prepare to respond to any potential damage and requests for assistance. It is estimated that over 15 000 deaths occur annually around the world as a result of severe weather. The National Climatic Data Center reports 15 tornado outbreaks in the United States that individually produced over \$1 billion in damage over a 10-year period ending in 2009. Flash floods are a significant hazard in Europe, with numerous individual events in the past decade again causing over \$1 billion in damage. Damage from the wildfires in Russia during August 2010 is estimated to be in excess of \$15 billion. Increasing worldwide population, urbanization, and greater dependence on complex technology-based infrastructure suggest that our risk exposure to the effects of severe weather is increasing. A single severe weather event that damages a critical piece of infrastructure could negatively impact an area for a long period of time.

Global estimates of the severe weather threat can be produced from reanalysis data. The conditions that favor significant severe thunderstorms are identified in the data for locations across the globe and the frequency at which these

favorable conditions occur is calculated. The resulting map highlights regions with the most persistent severe weather potential (Figure 1), such as central North America, southern South America, western and southern Africa, the Mediterranean region of Europe, southern and eastern Asia, and eastern Australia. While these areas have higher severe weather frequency, reports indicate that severe weather occurs on every continent except Antarctica, so no country is completely safe from the threat.

The global nature of the severe weather threat, and the disruption it produces, further underscores the value of providing severe weather forecasts that allow for actions to be taken to protect life and property. The forecast process is difficult, however, because severe weather events often occur on very small scales that are not well observed and the physical processes that produce severe weather are not completely understood. This combined lack of observational detail and physical understanding is partially compensated for by the

Figure 1 The yearly probability (%) of environments favorable for severe thunderstorms calculated from global reanalysis data over the years 1948–2008. Areas surrounded by a thick black line have a 5% or larger probability of favorable environments for severe thunderstorms, which equates to an average of 18 days per year.

presence of repeatable synoptic-scale atmospheric features for many of these events. Thus, the forecasting of severe weather is based largely upon knowledge of climatology, pattern recognition, and meteorological parameter evaluation, in which the human forecaster plays the crucial role. Pattern recognition and parameter evaluation approaches are applied to both observational data and numerical weather prediction model forecasts. The recent availability of forecasts from convection-allowing numerical weather prediction models, which can predict individual thunderstorms and their evolution, shows great promise although the optimal role these predictions will play in the forecast process is still being evaluated.

The primary missions of the Storm Prediction Center, a national center within the US National Weather Service, are to forecast severe weather events associated with thunderstorms and to provide fire weather outlooks. The severe weather forecasting mission has been part of the weather service since 1952 and is supported because of the rarity of severe weather events in any one locality and the recognition that these events span geopolitical boundaries. In some regions of the country, a local weather forecaster may experience a significant severe weather event once during an entire career. This requires the forecaster to make all the right decisions, based upon limited understanding and limited observations, the very first time a significant threat is encountered. In contrast, a forecaster at a center with national responsibility experiences significant severe weather events on many days each year. Thus, the experience base upon which to guide decisions grows rapidly and can be shared easily with local forecasters and the general public. Countries of smaller physical size than the United States may benefit greatly from a multicountry severe weather forecasting center.

In this article, the process of forecasting severe weather events prior to and during their development is discussed. This is not the same process as nowcasting, in which the present weather situation is monitored and linear extrapolation is used to predict future events as illustrated in Figure 2. The forecasting process does not necessarily involve a longer time scale,

but nonlinear methods and forecaster experience are used in the process. Severe weather forecasts typically extend from 0 h out to a week. Short-range forecasts (0–24 h) provide detailed guidance on the expected hazards, their location, and evolution. These forecasts use both observational data and numerical weather prediction model output in their creation. Forecasts for the next day and extending out to a week provide less detailed guidance, such as the expected coverage and intensity of the threat, and are based almost entirely upon output from numerical weather prediction models. While output from numerical weather prediction models contributes significantly to the forecast process, one should never lose sight of the fact that the human forecaster makes the process successful.

Elements of Forecasting

The forecasting process typically begins by defining a broad region of potential severe weather threat and then refining this area of potential threat so that the final forecast product is as specific as possible. This forecasting process requires knowledge of climatology and incorporates the techniques of pattern recognition and parameter evaluation. We assume that the forecaster has access to a standard suite of meteorological observations, including at a minimum data from surface stations and upper-air soundings, and also has access to numerical weather prediction model output. Real-time data from radars, satellite, radar wind profilers, lightning detection systems, and aircraft are also very useful. Observational data are typically analyzed first, to develop a picture of the atmosphere at the most recent observational time, followed by an analysis of numerical weather prediction model data to help gain an appreciation of possible scenarios and extend the forecast into the future.

Climatology

One of the first elements used in the forecasting of severe weather is knowledge of the climatology of the various types of severe weather events. Climatology increases awareness of where and when severe weather has occurred in the past, so that the forecaster is prepared and looking for indications of a severe weather threat on days when severe weather is known to occur. A comparison of the patterns of yearly cycles of mean monthly tornado and heavy rainfall (25.4 mm h^{-1} , which is used as a proxy for flash floods) over the United States indicates that the regions of highest probabilities for these two events are different (Figures 3 and 4). The area of highest heavy rainfall frequency is located to the south, southeast, or east of the area of highest tornado frequency. The event frequencies also are different, with heavy rainfall much more common than a tornado within 40 km of a given location. Knowledge of these patterns and their differences helps forecasters better anticipate when severe weather is most likely. There also are days when the potential for severe weather is high but the expected type of severe weather event (e.g., tornadic supercell or damaging windstorm) is unclear. Climatological information can help determine which event is most likely on a given day. However, the usefulness of climatology is dependent on the robustness of the severe weather reports used to create the climatology. Since

many severe weather events can be identified only by a human being watching the event unfold, public recognition and knowledge of severe weather influences the accuracy of the climatology. If the public is told that hail never occurs in their city, then it is very likely that if a hail event happens either it will not be reported or the report will not be accepted as accurate.

Climatological analyses further can be used to address the variability in the timing and location of severe weather events.

Annual cycles of various severe weather events can be generated for specific locations. These cycles highlight both the year-to-year reliability and the year-to-year variability of the severe weather threat at different locations (**Figure 5**). This information helps forecasters to anticipate when severe weather is more likely and also helps them to provide information to the public about why an apparently unlikely event – such as a tornado during the winter in the state of Mississippi (**Figure 5(b)**) – is not unusual. This region of the United States has

Figure 5 Probability (%) of a tornado within 40 km for (a) Lubbock, Texas, USA, and (b) Hattiesburg, Mississippi, USA, plotted versus day of the year (month/day). The probabilities were calculated using six different 5-year data sets, illustrating the robustness or the variation of the threat. The black line is the mean probability for the complete 30-year period. Locations of Lubbock and Hattiesburg shown in [Figure 3\(a\)](#).

a persistent low level of threat that peaks slightly in the early summer and the winter.

Pattern Recognition

Many repeatable atmospheric features have been associated with severe weather events. These synoptic-scale atmospheric patterns are observed by our present data networks and are used routinely by forecasters as the next step in assessing the severe weather threat. Composite charts, in which specific features found at different pressure levels within the troposphere are plotted on a single chart, are often used. These presentations allow forecasters to view the atmosphere in a three-dimensional perspective and can highlight the vertical relationships between synoptic features and selected parameter fields considered important for the type of event being forecast. Composite charts plotted for typical tornadic thunderstorm, damaging windstorm (derecho), and flash flood days illustrate that the synoptic and mesoscale features associated with these events are different, although there are also some similarities ([Figure 6](#)). Individual events do not always contain all of the features seen in these composite analyses, but a number of these features are likely to be observed. Composite analyses assist in defining the broad region of potential threat, which often can cover a large geographic region. More information is required to then develop the tailored forecast product the public needs.

Parameter Evaluation

Parameter evaluation techniques help to refine the region of severe weather threat determined from pattern recognition. These techniques are based upon our understanding of the physical processes that produce severe weather and have changed significantly over time as our understanding of these processes has advanced. Through numerical simulations of

severe weather events, special field experiments, and forecaster experience, the knowledge of the specific types of local environments in which severe weather occurs is growing. This knowledge leads to the development of various parameters that are used to assess and refine the severe weather threat.

Whereas pattern recognition focuses primarily upon the synoptic-scale features plotted on a map, parameter evaluation uses the vertical thermodynamic and wind profiles at a point location to provide guidance on the type of severe weather that can be expected. For example, thunderstorms require large values of convective available potential energy to produce updrafts strong enough to form large hail. However, we also know that updraft strength is not the only factor influencing hailstones and that the depth over which the hailstone is falling through temperatures above freezing is also important. A parameter could be designed to combine the value of convective available potential energy with the height of the freezing level into a single number. Tornadic thunderstorms are often associated with environments having very moist boundary layers topped by an inversion and steep mid-level lapse rates ([Figure 7](#)). However, tornadic thunderstorms also often have a low-level veering wind profile in which the scalar product of the velocity and vorticity vectors (called the storm-relative environmental helicity) is large. A parameter could be designed to combine information on the boundary layer moisture content, mid-level lapse rate, and storm-relative environmental helicity into a single number. Candidate parameters are often tested within a large database that contains the vertical environmental profiles associated with various severe weather events to determine if the parameters can discriminate between different types of severe weather. Successful parameters that quantify specific aspects of the vertical thermodynamic and wind profiles known to be associated with a certain type of severe weather event help further refine the severe weather threat region.

Figure 6 Composite charts for (a) tornadic thunderstorm, (b) derecho, and (c) flash flood days. Dark wind vectors indicate the position of the low-level jet (LLJ); white wind vectors indicate the position of the upper-level jet (ULJ); and smaller dark wind vectors indicate the 500 hPa flow patterns. SW denotes 500 hPa short-wave location, and the wavy line denotes 500 hPa dewpoint temperature depression (DD) isoline in ($^{\circ}\text{C}$). L denotes the surface low-pressure center. Dash-dot line indicates the 850 hPa dewpoint temperature (T_d) isoline; dash-dot-dot line indicates the surface dewpoint temperature isoline; dash-dash-dot line indicates the 700 hPa dewpoint temperature depression isoline; and dash-circle line indicates position of the dryline. Cold and warm frontal boundaries are denoted using standard convention. Polygon-shaped shaded area indicates where the threat of the event is focused. Part (a) after Barnes, S.L., Newton, C.W., 1986. Synoptic and meso- α aspects of flash flood events. *Bulletin of the American Meteorological Society* 60, 115–123.

Parameter evaluation is used to reduce or increase both the areal extent and the magnitude of the severe weather threat within the broad threat region defined from pattern recognition and an awareness of climatology. If one or more parameters are unfavorable for severe weather, then the region of severe weather threat may be reduced or these factors may be discussed in the forecast text. Parameter evaluation can also lead to areas being identified as having a larger threat if many of the parameters are favorable. Through this approach, the threat region is modified and often reduced in size. Unfortunately, a variety of environmental factors influence

the development of severe weather. It is not always clear in advance whether one marginal ingredient (such as instability) can be offset by sufficient vertical wind shear to develop an isolated severe storm or will instead result in more widespread severe weather.

Convection Initiation

Convection initiation is one of the most difficult aspects of severe thunderstorm forecasting. It is not uncommon for all the

Figure 7 Skew- T log p diagram of mean temperature (red line), dewpoint temperature (green line), and winds from tornado proximity soundings. Full wind barb is 5 m s^{-1} . Hodograph plotted in upper right for winds at surface and at 850, 700, 500, 300, and 200 hPa levels showing significant curvature of the wind profile with increasing height. Values of storm-relative environmental helicity (SREH) and bulk Richardson number shear (BRNSHR) calculated from this wind profile are shown. SREH calculated using a climatological storm motion based upon the mean wind in the 850–200 hPa layer. Thermodynamic sounding after Fawbush, E.J., Miller, R.C., 1953. A method for forecasting hailstone size at the earth's surface. *Bull. Am. Meteorol. Soc.* 34, 235–244; wind profile after Maddox, R.A., 1976. An evaluation of tornado proximity wind and stability data. *Monthly Weather Review* 104, 133–142.

above factors to indicate that the storm environment is favorable for severe weather, but determining whether or not storms will develop is very challenging to forecast accurately. Three elements are necessary for the development of thunderstorms: low-level moisture, steep mid-level lapse rates, and lift. Many of the above analysis techniques evaluate the low-level moisture content and steep mid-level lapse rates, but whether or not a parcel of boundary layer air can reach its level of free convection, above which it is warmer than the environment and rises freely to near the tropopause, is not easy to assess. Even when we believe it is likely that deep convection will develop, specifying the time and location of initiation can prove very elusive. The difficulty of forecasting convection initiation is apparent in both numerical weather prediction model forecasts and human forecasts.

Convection initiation is a small-scale process and is influenced by small-scale features such as boundary layer thermals and rolls, terrain, and vegetation contrasts; by mesoscale features such as cold surface outflows from previous convective activity, drylines, gravity waves, bores, and sea breeze fronts; and by synoptic-scale features such as cold fronts, warm fronts, jet streaks, and upper-tropospheric troughs. A single feature may control convection initiation for one event, while a number of these features may interact synergistically to produce the lift needed to initiate deep

convection for another event. Several features also may interact synergistically to suppress convection initiation or may act in opposing directions, leading to great uncertainty in whether or not convection will develop. It is no wonder that predicting convection initiation is difficult. In one case, strong surface outflows of evaporatively cooled downdraft air from two separate areas of ongoing thunderstorms were observed to collide and a new area of convection was forecast to occur in the region of collision. No new convection developed. Postanalysis with special data indicated that a collision of upper-level anvil outflow also occurred over a large region above the surface, producing sinking motion that was strong enough to inhibit further convection initiation (**Figure 8**). The multiscale processes often associated with convection initiation are beyond our present ability to observe using current observational facilities, while many of these processes are not understood completely. It should be no surprise that accurate forecasts of convection initiation continue to elude even the best forecasters.

The difficulty of forecasting the exact details of convection initiation was one factor that led to the development of the severe local storm watches for both tornadic thunderstorms and severe (nontornadic) thunderstorms in the United States. A severe local storm watch means that severe local storms are likely if storms develop. These watches are usually issued for periods of 4–6 h over a region of 52 000 km^2 and often have a quadrilateral shape. They are intended to focus attention on a smaller region in which the forecaster believes there is a significant threat of severe weather and in which convection initiation is most likely to occur first within a broader region of threat. Watches are an effective way to alert the public to stay abreast of current developments so that they can take appropriate action if necessary.

Figure 8 Schematic of hypothesized mesoscale features and circulations showing observed colliding low-level storm outflows and the perturbation upper-level converging anvil outflows. Lower schematic depicts hypothesized vertical motions driven by the convergence of both upper-level and low-level outflows through a vertical cross-section connecting points A, B, C, and D in the upper schematic. After Stensrud, D.J., Maddox, R.A., 1988. Opposing mesoscale circulations: a case study. *Weather Forecasting* 3, 189–204.

Evolutionary Concerns

Once convection develops, or a severe weather event is underway, it is necessary to determine how long the severe weather threat will last, what additional areas will be affected by the event, and how the structure of the developing system will evolve. In many cases, it is not unusual for the type of severe weather threat to change. The initial threat may be from isolated tornadic thunderstorms, but over time these thunderstorms may merge and form a line of convection or a mesoscale convective system. At this later time, the severe threat may be flash flooding or damaging straight-line surface winds. This change in the severe weather threat often requires a different type of response from local officials such as emergency managers and is another important component of severe weather forecasting.

Forecasting thunderstorm evolution after initiation is challenging. A number of factors influence whether or not isolated storms will grow upscale into a convective line and, if they do, how quickly this evolution will occur. These factors include the evolving environmental conditions; the number, separation, and alignment of storms; the strength of thunderstorm cold pools; interactions between cold pools; and the ability of cold pools to initiate new storms along their leading edge. Results from convection-allowing numerical models suggest that while the models can provide useful information on convective mode, predictions of upscale growth are difficult.

Numerical Models and Ensembles

Analyses and forecasts from numerical weather prediction models provide the forecaster with valuable information on the current and possible future states of the atmosphere. Model analyses are important as they combine, in a dynamically consistent manner, all the available observations with a previous model forecast to form a three-dimensional snapshot of the atmosphere at a particular time. Some models produce these analyses at hourly intervals, allowing forecasters to assess the rapid changes in atmospheric structure often associated with severe weather. The ability to predict how the atmosphere will evolve over the next few hours also is very important, because patterns and parameters that affect severe weather potential are rarely static. They continuously undergo change, and small changes in some parameters can lead to either severe weather occurring or no storms at all. Since model-generated analyses and forecasts are available at regular time intervals and over a three-dimensional grid that covers the forecast area of interest, the same techniques used for assessing the severe weather threat with observational data can be used to assess the severe weather threat using model analyses and forecasts. These techniques include pattern recognition and parameter evaluation. Model forecasts also provide guidance on where and when convection will develop, which can help the human forecaster refine the region of threat. However, the added difficulty is that numerical weather prediction models are not perfect and often have biases, so one must account for these model errors in the preparation of the forecasts. An additional challenge arises because known biases and systematic errors often change as numerical models are updated. This

model improvement process requires forecasters to continuously monitor model performance.

Measures of numerical model skill indicate that the operational models in use today are much better at forecasting the synoptic-scale features of the atmosphere than were the numerical models in use 20 years ago. Unfortunately, the skill of numerical models to forecast the small-scale and mesoscale features so important in the forecasting of severe weather has not seen a similar increase. Thus, even though numerical models predict details such as convection initiation and evolution, these smaller-scale fields cannot be treated with the same certainty as the synoptic-scale patterns. Convection is one of the most difficult forecast fields to predict accurately, since it is influenced strongly by all the other physical processes in the numerical model and is sensitive to mesoscale variability in initial conditions that are not resolved by standard observational data networks.

One recent addition to the operational model suite in several countries is a short-range ensemble forecast system. An ensemble is a group of model forecasts valid over the same time period, with each ensemble member starting from slightly different initial conditions. Some ensemble systems also use several different models or different physical process parameterization schemes within the same model. Ensembles allow forecasters to assess in what ways the model predictions contained within the ensemble are the same and in what ways they are different. This assessment provides information that can be used to develop greater confidence in specific outcomes, say when all the model predictions agree, and to determine how alternative outcomes seen in only a few of the predictions would influence the severe weather threat. If these alternative outcomes lead to significant changes in the expectations of severe weather, then the forecaster can determine how best to communicate this information to the public and will carefully monitor the observations to determine if this outcome becomes more likely over time. Ensembles have revolutionized the forecast process as they allow for a richer exploration of possible future atmospheric states and their relation to severe weather, thereby reducing the number of severe events that are not anticipated.

Due to the large computational cost of running an ensemble system, the ensemble model grid spacing is usually larger than in single deterministic forecast models. Thus, forecasters have both an ensemble forecast system and a high-resolution deterministic forecast system available for their use. This situation gives the forecaster the ability to view the high-resolution deterministic forecast from the perspective of the ensemble output and determine how they agree or disagree. This assessment can increase or decrease forecaster confidence in the solutions provided by the single high-resolution forecast. However, high-resolution ensembles in which convection is no longer parameterized and instead occurs on the grid scale are being explored in operations. One such convection-allowing ensemble forecast has been produced experimentally for the National Oceanic and Atmospheric Administration's Hazardous Weather Testbed by the Center for Analysis and Prediction of Storms at the University of Oklahoma. An example from this experimental storm-scale ensemble is shown in a case study. In addition, a storm-scale ensemble of opportunity currently is being

produced in real-time that is comprised of forecasts from seven deterministic convection-allowing model runs. While most of these forecasts are nonoperational and subject to occasional outages, the results from this ensemble are encouraging.

Forecasting Severe Weather Events

The forecaster develops a likely evolution of the severe weather situation through an examination of all the observational and model forecast information using pattern recognition and parameter evaluation techniques as well as past experience. Conceptual models of various severe weather types also are very helpful in this forecast process. Close monitoring of the evolving atmospheric conditions using observations and analyses helps the forecaster determine if any changes to the severe weather forecast are warranted. Forecasters also assess the accuracy of the model forecasts by comparing the model fields with all available observational data. Computer workstations that can display simultaneously a multitude of observations (such as surface and upper-air observations, and radar and satellite imagery) and model analyses and forecasts are very helpful. This nearly continuous situational awareness process, which combines observational assessment with model forecast evaluation, may lead to adjustments in the severe weather forecasts. The forecast process continues as each new piece of information is made available to the forecaster.

It is difficult to illustrate the process of severe weather forecasting without examining an event that shows the complexities one encounters when using observations and numerical model output. Therefore, a severe weather event that illustrates the diversity of the forecast issues is discussed. Since this is a brief analysis of an event that has already happened – so that the ‘answer’ to the forecast problem is already known – the importance of particular synoptic features

and meteorological parameters is typically clearer now than prior to the event.

Tornadoic Thunderstorm Event: 17–18 June 2010

Since strong and violent tornadoes are almost always associated with supercell thunderstorms, a subset of all thunderstorms that have strong, persistent mid-level rotation coincident with the storm updraft, the forecasting of significant tornadoes is very similar to the forecasting of supercell thunderstorms. Environmental factors that are favorable for supercell thunderstorm development are moderate to large values of convective available potential energy and vertical wind shear, often evaluated by calculating the storm-relative environmental helicity. Many studies have demonstrated that these two factors lead to the development of mid-level rotation in thunderstorms, the key characteristic of supercells. It has recently been suggested that the development of low-level rotation in thunderstorms is influenced by the wind shear and moisture near the ground. Thus, once a prediction of supercell thunderstorms is made, forecasters examine the wind shear over the lowest 1 km and cloud base height to refine the tornado threat.

There were reports of 66 tornadoes across the states of Iowa, Minnesota, and North Dakota on 17 June 2010, with numerous additional reports of hail and damaging winds (Figure 9). Climatology indicates that the frequency of tornado reports in Minnesota reaches its yearly maximum in late June, so a forecaster would be very aware of any potential tornado threat on this day. The annual cycle of the hail threat parallels the tornado threat, and damaging winds are also possible even though this threat actually peaks in July. The threat for all three of these severe events is relatively high during late June in Minnesota.

A composite analysis of conditions during the event from 0000 UTC 18 June (Figure 10) shows many similarities to

Figure 9 Reports of tornadoes (red), hail (green), and damaging surface winds (blue) during the 24-h period from 1200 UTC 17 June 2010 through 1200 UTC 18 June 2010 over the United States collected by the Storm Prediction Center of the United States National Weather Service. Image courtesy of the Storm Prediction Center.

Figure 10 Composite chart for atmospheric conditions over the northern United States valid 0000 UTC 18 June 2010. Dark wind vector indicates the position of the low-level jet (LLJ); white wind vector indicates the position of the upper-level jet (ULJ); and smaller dark wind vectors indicate the 500 hPa flow pattern. SW denotes 500 hPa short-wave location, the dash-dot line denotes 850 hPa dewpoint temperature (T_d) isoline ($^{\circ}\text{C}$), and dash-dot-dot line denotes the surface dewpoint temperature isoline. L denotes the surface low-pressure center, with cold and warm fronts indicated using standard conventions. Polygon-shaped shaded area indicates the region of threat for tornadic supercell thunderstorms. MN indicates the state of Minnesota.

tornado composite analyses. These features include a cold front advancing from the west, deep low-level moisture to the east of the front, a strong southerly low-level jet that advects moisture northwards, and an upper-level southwesterly jet with an associated short-wave trough. Parameter evaluation techniques further support the threat for supercell thunderstorms. Values of convective available potential energy exceed 1000 J kg^{-1} across the threat area, while the storm-relative environmental helicity values exceed $300 \text{ m}^2 \text{ s}^{-2}$ and are well above the threshold values typically associated with

supercell thunderstorms. Now that the threat of supercell thunderstorms has been diagnosed, parameters are examined to refine the tornado threat. Model analyses and observations indicate the wind shear in the lowest 1 km above ground is very strong and the cloud base height is low, suggesting that tornadoes are likely if supercell thunderstorms develop. Thus, the threat for tornadic supercell thunderstorms is supported by both the composite analysis and parameter evaluation.

Numerical weather prediction model forecasts of this event also support the conclusion that supercell thunderstorms are likely. Both composite analysis and parameter evaluations applied to model forecasts valid at 0000 UTC 18 June suggest a threat for tornadic supercell thunderstorms (not shown). However, even more impressive is a 22-h forecast of radar reflectivity from a convection-allowing model run, provided by the NOAA National Severe Storms Laboratory, that compares reasonably well with radar observations at 2200 UTC 17 June 2010 (Figure 11). The forecast shows a combination of isolated storms and more contiguous lines of convection that are located $\sim 50 \text{ km}$ to the west of the observed thunderstorm locations. This size of placement error is very good for a 22-h forecast, while the type of convection produced in the model forecast closely mirrors the reflectivity structures seen in the radar observations. The information provided on the type of convection is particularly useful to forecasters and further supports the idea that isolated thunderstorms are likely on this day.

Further support for supercell thunderstorms on this day comes from a 24-h convection-allowing ensemble forecast valid at 0000 UTC 18 June provided by the Center for Analysis and Prediction of Storms at the University of Oklahoma. Model forecasts of updraft helicity, a field that is used to identify rotating thunderstorms, show high probabilities across Minnesota (Figure 12). This result indicates that supercell thunderstorms are present in many of the ensemble members, thereby reinforcing the conclusions based upon a single model forecast, composite analysis, and parameter evaluation. The

Figure 12 Probability (%) of updraft helicity values exceeding $25 \text{ m}^2 \text{ s}^{-2}$ from a storm-scale ensemble forecast valid 0000 UTC 18 June 2010 produced by the Center for Analysis and Prediction of Storms at the University of Oklahoma. Updraft helicity is a parameter that is used to diagnose rotating (supercell) thunderstorms in numerical weather prediction model forecasts.

consistency in these evaluations of the severe weather threat provides the forecaster with very high confidence that the event will unfold as anticipated.

Future Directions

As computer power continues to increase, it is likely that numerical weather prediction models will be able to produce convection-allowing ensemble forecasts over large regions of the globe that can explicitly resolve individual thunderstorms in great detail and account for imperfections in the model initial conditions and physics. New observational systems, such as geostationary satellites, phased array radars, national surface mesonetworks, and lightning mapping arrays, will improve our ability to sample the atmosphere and construct more accurate analyses of atmospheric conditions. These improvements in both observations and model forecast ensembles will help human forecasters define the severe weather threat and communicate it effectively to the public. The advent of smart phones is already changing how weather information is disseminated to the public, and continued rapid changes in this area are expected.

Some have taken the enhanced observation and numerical modeling capability to mean that the need for human

forecasters will be reduced, particularly since numerical model guidance will have so much detail. However, the atmosphere is a complex system and this complexity may be greatest for severe weather events where nonlinear processes play a significant role in their evolution. Processes like convection initiation will continue to be difficult to forecast accurately by both numerical models and forecasters. Advances in our scientific understanding of the processes that lead to the development of severe weather will continue to alter the parameter evaluation methods mentioned and may even lead to improved composite analyses. Therefore, the need for human forecasters and their ability to assimilate vast amounts of information quickly and incorporate recent scientific advances into their work will remain for the foreseeable future.

Wildfire Weather

J Coen, National Center for Atmospheric Research, Boulder, CO, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

Weather across timescales influences wildland fires, from microscale temperature and humidity effects that determine whether a fire ignites, to thermal diurnal wind and humidity patterns and topographic flow effects on the wildfire spread rate and direction, to seasonal and interannual weather patterns favoring large fire growth. Dynamic feedback of heat and momentum fluxes between a fire and the atmosphere creates universally observed fire phenomena as fires create their own weather. Fires affect weather and the environment, as fire emissions reduce air quality through increased particulate levels and gases that chemically evolve to degrade regional air quality. Fires contribute to climate, as they release greenhouse gases and particulates that affect cloud microphysics and radiative properties.

Introduction

Weather is one of the most significant factors influencing wildland fires, as weather conditions from the seasonal to the instantaneous play a role in where fire occurs, how it spreads, the intensity of the burning, and whether or not the fire displays extreme and erratic behavior. Wildfires in turn make their mark upon the atmosphere, releasing as much as several megawatts of heat per square meter and releasing smoke composed of aerosol particles, water vapor, and other gases as well as re-releasing pollutants captured by the biomass. The connection between wildfires and their environment is even more complicated, however, because complex dynamical interactions can occur when the atmospheric winds caused by the fire feed back to influence the fire itself. Before examining the complex interplay between a fire and the atmosphere, the basic elements required for a fire will be discussed. Three elements (the 'fire triangle') must be present for a fire to occur and continue. There must be fuel (any material, living or dead, that can burn), oxygen for the fuel, and the fuel condition is a result of the recent weather as well as the year's pattern, especially that of precipitation; atmospheric winds may fan the fire with oxygen-rich air; and heat is often provided for ignition by lightning strikes or transferred to new fuel by wind, for example, by the lofting of burning embers.

Three environmental factors affect wildland fire behavior: weather, fuel characteristics, and topography. Fuel factors include the type, moisture, size, shape, amount, and arrangement. Topography factors include the orientation toward the sun, the slope, and features such as narrow canyons and barriers such as creeks, roads, and unburnable fuel. Of the three environmental factors, weather (including factors such as wind, temperature, relative humidity (RH), and precipitation) is the most rapidly changing. Weather phenomena that bring changes such as cold fronts, foehn winds, thunderstorm downdrafts, sea and land breezes, and diurnal slope winds can be particularly dangerous, as they can suddenly change the fire's direction and behavior. Weather also influences other factors of fuel and topography, by controlling the fuel moisture through precipitation, RH, and winds, and by complicating the fire-accelerating effect of slopes with topographically induced flows. Additionally, though weather can influence wildfire behavior through many

pathways, it has long been recognized that intense fires 'create their own weather.' That is, the heat and moisture created by the fire feed back into the atmosphere, creating intense winds that drive the fire's behavior, sometimes overwhelming the effect of ambient winds. Research studies have only begun to investigate this dynamic interaction between wildfires and the atmosphere.

Effects of Weather on Fires

Fire is the release of energy as heat and light when, through a chemical reaction, oxygen combines with a combustible (burnable) substance at a sufficiently high temperature, involving both heat transfer and fluid dynamics. Weather affects fires on scales ranging from persistent, seasonal patterns related to global circulation patterns down to small-scale, rapidly changing conditions in the fire's environment by altering the fluid dynamics of the air in which the fire occurs and factors that control the combustion of wildland fuels.

Overall, human-caused fires are the most prevalent sources of fires around the world, often set to clear land for agriculture. However, in the United States, about 80% of fires are caused by natural sources, nearly all by lightning strikes. When lightning strikes or an active firebrand lands on fuel, ignition is not certain. The probability of ignition (the 'lightning ignition efficiency') depends on the duration of the lightning strike or contact, fuel moisture and temperature, as well as other non-weather-related elements such as fuel depth.

Wildland fuel consists of ground material such as duff and forest litter, as well as needles, leaves, twigs, and larger woody materials of trees. Wood is made up of cellulose (cell walls) and hemicellulose (which is readily pyrolyzed), lignin (which mainly forms char), extractives (primarily hydrocarbons), lipids (a ready source of combustible volatiles), and ash content (which exerts a suppressing effect). Solid wildland fuels such as wood do not burn directly; ignition has several stages. During a pre-ignition phase, fuel must be heated by an outside source and its temperature rises toward the ignition temperature (about 390 °C for fuels composed mainly of cellulose); thus, the ignitability depends on the fuel's initial temperature, as well as its thermal properties. This ignition temperature is

well above the boiling point of water, so all the water present in the fuel must also be vaporized before ignition will occur. At higher temperatures (200–340 °C), fuel undergoes pyrolysis, the thermal decomposition into an envelope of flammable gases, semivolatile tar, and a solid char. These volatile gases (volatile organic compounds (VOCs)) burn in flaming combustion in a narrow envelope of flame around the fuel-rich zone only where the oxygen (diffusing inward from free air) and fuel (diffusing outward) are mixed in certain proportions above the ignition temperature to produce rapid oxidative chemical reactions that emit visible light called a flame. Some VOCs volatilized ahead of the flame front escape the combustion process and are found unaltered in the smoke plumes. Ignition is the transition from pre-ignition to combustion, the temperature at which external heating is no longer required. Once ignition is reached, the heat generated by combustion brings other fuel to ignition, continuing the process. Finer fuels such as grass carry the flame front (Figure 1); the speed at which this interface between burning and unburned fuel travels

Figure 1 The fire process. Fuels are usually a mixture of dry fine and heavy fuel. Heat preheats the fine fuel. Moisture is boiled off. Tar appears as visible smoke. A cloud of combustible gases is formed. Heat ignites the combustible gases. Flames from burning fine fuel particles preheat larger fuel particles. Gases from larger fuel particles ignite. The fine fuel begins to burn by glowing combustion. Ash is formed. Pre-ignition, ignition, and flaming and glowing combustion are occurring in different parts of the fire. Smoke particles and CO result from incomplete combustion. Wood collapses because the applied heat weakens cellulose. Gray mineral ash coats the fuel surface. Ash must be knocked off to prevent smothering. The fire is extinguished. Most of the cellulose fuel has reacted with oxygen to form CO₂ and water. Photograph courtesy of the U.S.D.A. Forest Service.

is called the fire spread rate. However, combustion may not always involve a flame. After flaming combustion has consumed most of the volatile substances, the remaining solid carbon may burn by smoldering (surface oxidation, also called glowing combustion).

The thoroughness with which combustion consumes the fuel (the ‘combustion efficiency’) varies. Most laboratory studies of gaseous combustion have been carried out with well-mixed (‘premixed’) fuel–air mixtures, but in natural fires, mixing of fuel and air is an integral part of the burning process – these flames are known as diffusion flames. Consequently, combustion is less efficient, burning only where there is a sufficient mixture of fuel and oxygen. In a free-burning fire in the atmosphere, enough air is usually entrained into the flame to burn all the combustible gases; however, some products of incomplete combustion survive and are released to the atmosphere. If combustion is not complete, some of the volatile products remain as very small, suspended drops of fluid, along with minute carbonaceous particles formed in the flame under conditions of low oxygen and high temperature. These make up the particulate portion of smoke that reduces visibility. Carbon monoxide (CO) is also a product of incomplete combustion, and the ratio of CO to total carbon content including CO₂ (a product of complete combustion), indicates the degree of complete combustion. Extinction is the termination of combustion and occurs when one of the three elements of the fire triangle is removed (e.g., there is no more fuel, the oxygen supply is cut off, or the heat required to bring fuel to ignition is removed by dousing with water).

Small-Scale Effects of Temperature and RH on Combustion

Atmospheric temperature, RH, and wind directly affect combustion rates or the fluid dynamics of the air in which combustion occurs. Higher fuel and ground temperatures make it easier for fire both to ignite and to burn, because less heat must be added and less time is required to bring the fuel’s temperature to the ignition temperature. This is one reason why fire activity usually peaks in the late afternoon. Solar radiation can also add to the fuel temperature – in some climates, there can be a 25 °C difference in fuel temperatures between sunny and shaded spots. Cloud cover or dense smoke in the fire’s own smoke plume can shade the fire and reduce fuel temperatures.

A fire’s potential is very sensitive to the dead fuel moisture, defined as the percentage of mass of water to the mass of dry fuel. The equilibrium moisture content is the value the moisture content would approach if the fuel were exposed to constant temperature and RH for an infinite time. However, atmospheric conditions surrounding fuel seldom remain the same for long, and different fuels can be classified according to the time it takes them to adjust to changes in the atmosphere. The fuel moisture in dead fuels (fuels that are no longer part of a living plant or tree) is determined by ambient RH, temperature, and precipitation, and responds to changes in its environment with a time lag proportional to the fuel’s diameter; this time lag is loosely defined as the time it takes a fuel particle to reach two-thirds of the way to equilibrium with its local environment. The moisture content of fine fuels such as twigs, needles, and grass adjusts quickly to ambient conditions, with a timescale of minutes to an hour. Larger diameter fuels take longer to adjust

to ambient moisture conditions; for example, logs that are 15 cm in diameter have an average time lag of about 36 days. (For clarity, this time lag is generally expressed in hours, and fuels are often characterized as having 10-, 100-, or 1000-h fuel moistures.) For this reason, large precipitation rates over a short time will not raise fuel moisture as much as lesser rainfall rates over a longer time. Wood that may ignite easily at fuel moistures of a few percent may smolder at fuel moistures of 13%, for example, and not burn at all if the fuel moisture rises to 15–20%. Thus, lightning strikes in relatively cool, moister evenings can cause fire starts that smolder overnight (or even for weeks) before becoming active when conditions for fires improve, as daytime temperatures rise and humidity drops, and fuels dry to the point where flaming spread is possible. In the western United States during the summer, dry lightning storms – lightning storms in which negligible precipitation reaches the ground – commonly ignite many fires. These storms, characterized by deep, dry adiabatic layers and midtropospheric moisture, support high-based thunderstorms that nevertheless produce many lightning strikes.

Wind, either ambient or induced by the fire itself, encourages combustion and fire spread by drying the fuel (by increasing the evaporation rate), by ventilating the fire by increasing the supply of oxygen, by influencing the direction of fire spread (generally directing it toward fresh fuel), and by tilting the flame forward and closer to unburned fuel ahead of the fire that may be warmed and dried by radiant heat, a process very dependent on proximity to the flame. The relative importance of these convective and radiative effects is still unclear.

Atmospheric stability is recognized as an indicator of fire behavior, as fires purportedly burn less intensely when air is stably stratified. A physical basis for this consensus is that a stable atmosphere is averse to vertical motions and thus limits the updraft strength over a fire (limiting the convergence at its base, limiting the winds ventilating the fire), while a super-adiabatic surface layer would enhance any perturbation caused by a fire. However, this may also partially be attributed to atmospheric conditions that accompany stable atmospheric stratifications, an example of which is seen during inversions. An atmospheric inversion is a layer in the atmosphere where the atmospheric temperature is steady or increases with altitude. Inversions often form at night near the surface and are common during calm, settled weather. They are an important factor in fire behavior, because when an inversion starts to lift or break, fire behavior can change abruptly, as winds pick up, surface temperatures rise, and RH drops. Similar to inversions, other atmospheric temperature structures called thermal belts play into fire behavior. Thermal belts of relatively warm air may form midway upslopes in mountainous areas. The top of the night inversion is usually below the main ridges. The height of the warmest air temperature is at the top of the inversion. From the top of the inversion, the temperature decreases as one goes farther up or down the slope. This region of warmer air (with accompanying low RH) is called the thermal belt. Within the thermal belt, wildland fires can remain active throughout the night.

Subsidence, the large-scale sinking of air often associated with high-pressure systems, can also play a role in fire behavior. As air from higher elevations in high-pressure systems descends

to lower elevations, it warms and dries. Although the air is stable, subsidence can lead to increased fire activity as this warmer and drier air sinks to the surface.

A negative vertical wind shear – that is, winds that decrease with height – has long been cited as a contributing factor to intensification of fires, but the dynamics through which this may occur have not been explained.

Indicators of the potential severity of wildfires can be designed by combining known factors. For example, the widely used Haines Index (HI) is calculated by combining the vertical temperature difference between the 70- and 50-kPa atmosphere levels (as a proxy for lapse rate) and the temperature and dew point difference at 70 kPa (indicating the dryness) to produce a number that indicates the potential for fire growth. The stability and moisture terms are each assigned values between 1 and 3 that, when added together, result in an index that varies from 2 to 6. An HI of 2 or 3 indicates a relatively moist, stable air mass with a very low potential for large wildfire growth, while a value of 6 indicates a dry, unstable air mass with high potential for large growth and extreme behavior of wildfires. HI values of 4 and 5 suggest low and moderate potential, respectively. Even though the effects of wind are not factored into the HI, the index has been shown to correlate well with rapid fire growth.

Diurnal Variability and Changing Weather Patterns

The daily diurnal cycle in temperature and RH, characterized approximately by a sinusoidal pattern with a maximum RH and minimum temperature in early morning, is a crucial window of opportunity in fire suppression. This nighttime recovery in temperature and RH is the norm, especially in high, dry regions, where nighttime temperatures can drop as much as 25 °C as radiative cooling leads to a cool, stable nocturnal boundary layer. This period is known as the ‘nocturnal lay-down,’ as fires subside at night in low temperature, high RH conditions, offering an opportunity for suppression. Exceptions can occur if there is nighttime cloud cover, which warms the surface through radiative heating, or winds that dissipate the stable layer and encourage vertical mixing.

Changes in weather conditions can lead to unpredictable fire behavior, as they can suddenly change the fire spread rate, direction, and fire intensity. Such changes include the following:

- Pressure gradient winds related to synoptic-scale weather patterns.
- Cold fronts, which bring erratic, gusty winds, and wind shifts after the frontal passage.
- Regional downslope winds, such as foehn winds in the Rockies and Santa Ana winds in California. These strong, dry winds may blow for days with gusts up to 50 m s⁻¹, exacerbating fire behavior while decreasing fuel moisture.
- Thunderstorms that can cause strong downdrafts, gusty surface outflows of 30 m s⁻¹ (higher for microbursts), and lightning.
- Marine-related features such as sea and land breezes that affect the winds, humidities, and temperatures in coastal areas.
- The breakup of a temperature inversion.

- Diurnal slope winds. In mountainous areas, heating of the slopes by solar radiation during the day leads to upslope winds of several meters per second during the afternoon, and cool drainage winds that move downslope during the night and early morning.

In summary, fires benefit from sustained high temperatures, low RH (single digits), dry fuels, strong winds, no RH recovery overnight, dry lightning, passing dry thunderstorms, and gusty winds. These are conditions that often coincide, resulting in extreme behavior such as spotting, crowning, torching of trees, uphill 'runs,' rolling debris, and sudden flare-ups that push fires across firebreaks and rapidly increase their size. Fires are hindered by afternoon cloud cover, moisture, still air, and sustained rain. In the United States, if weather conditions are forecast to include hot, dry days combined with high winds that could result in extreme fire behavior, or if extensive fire starts within the next 24 h are likely (particularly in the worst-case scenario of developing thunderstorms with dry, gusty winds and dry lightning), a fire weather forecaster issues a 'Red Flag Warning.' A Fire Weather Watch is issued when Red Flag conditions are expected within the following 72 h.

Seasonal and Interannual Weather Effects on Fire

Patterns and variability in weather on longer timescales affect wildfire activity primarily by affecting fuel moisture – prolonged periods of hot, dry weather can leave vegetation cured like tinder. The role of climate is most apparent in the regionally synchronized outbreaks of wildfires in particular years that have occurred for centuries. Broad regions of fire-enhancing weather are often associated with the biggest resource losses due to demand for suppression simultaneously in many spots. For example, 6 out of the 10 largest fires of 1999 in the United States were located in northern Nevada, 5 of which began over a 3-day period. Even though the connection of seasonal climate variability to wildland fires appears intuitively obvious – that droughts are correlated with wildland fires – the predictive nature of this relationship is poorly understood. For example, in some ecosystems, the drought–fire relationship also involves time lags with previous moisture conditions. In the Southwest United States, when an extremely dry winter–spring follows a wet spell (when the growth and accumulation of fuels is encouraged), exceptionally large areas burn the following summer. In some areas of the Northwest United States and Nevada, the fire risk at the season's peak is only weakly correlated with current climate conditions, and is more strongly linked to conditions 10–18 months before.

The interannual variability arising from the El Niño/La Niña episodes of the Southern Oscillation (SO) phenomenon is often cited as a factor in weak/severe wildfire seasons, respectively, for the United States (the reverse for Indonesia and Australia), but usefulness as a predictive tool is limited to certain regions. Interdecadal changes in fire–climate relationships in the Southwest United States parallel evidence of shifts in the frequency or amplitude of the SO over the past three centuries, where high correlations between fire and climate signals reflect periods of high amplitude in the SO and rapid

switching from extreme wet to dry years. Weak correlations are associated with a decrease in SO frequency or amplitude.

A research challenge is to separate the climate impacts on wildfire areal extent from anthropogenic effects that confound the climate relations, such as how decades of fire suppression and associated fuel buildups have compounded the effect of drought, and how some land use policies have allowed flammable non-native species to intrude into shrublands.

Dynamic Interactions between a Fire and the Environment

A fire is a continually propagating phenomenon and spreads by igniting new fuels along its outer perimeter. The leading part of the fire line is called the 'head' and is the fastest spreading. The slowest-spreading part is called the backing region, where the fire creeps against the wind. The fire spread rate is measured from a point on the fire line in a direction perpendicular to the perimeter. The spread rates can range over 3 orders of magnitude, from a barely creeping fire to about 6.7 m s^{-1} (the equivalent of a 4-min mile running pace). Fires spread most rapidly in the direction of the local wind and, in the absence of other factors, upslope on terrain. Slope and wind increase the spread rate in a similar way, by decreasing the angle between the flames (and the strong convective updraft in the fire circulation) and the fuels ahead of the fire. This could cause an increase in the flame spread rate by the increased radiant flux preheating and drying fuel ahead of the flames or repeated contact by flames; thus, the effect is particularly effective if the fire is spreading up a steep slope.

Wind enhances the spread of a fire front in a similar way. This effect increases approximately exponentially with wind speed up to a critical wind speed, at which extinction, or blowout, occurs. Although blowout is not believed to occur naturally in wildland fires, it is the basis of some fire suppression strategies, and works by distorting the reaction zone within a flame by stretching it thin so that fuel vapors have a much shorter period in which to react. If the reaction zone is too thin, combustion is incomplete and the flame is effectively cooled ultimately below the ignition temperature where it cannot be sustained.

Fire can also grow by igniting fuel outside its perimeter by spotting, in which burning embers are carried distances from inches up to many kilometers from the fire either by the ambient wind or by the fire's convection column before being dropped. This mechanism is particularly prevalent in Australian fuel complexes, where eucalypt bark provides copious numbers of flaming brands that can land up to 30 km ahead of the main fire.

Examples of Atmosphere–Fire Coupling

Fires sometimes exhibit extreme fire behavior, when the fire behaves in ways that preclude direct fire suppression. Examples of this are high spread rates, crowning (when the fire climbs into the tree canopies, where it travels rapidly), spotting, the presence of fire whirls (vortices of fire often seen along fire lines), a strong convection column indicative of intense burning, torching of trees (a sudden ignition of an entire tree),

and tall flames (sometimes 65 m above tree height). In these situations, it is difficult to predict what a fire may do next, because the fires often behave erratically and sometimes dangerously. Research suggests that the cause of extreme behavior is an interaction of the fire with its atmospheric environment. Numerous examples of interesting behavior result from this type of interaction.

Fire whirls

The intense buoyancy released into the atmosphere by a fire causes strong convective updrafts that create a strong convergence into its base, creating intense winds near the surface that drive the fire's behavior, sometimes overwhelming the winds in the fire's environment. Vorticity is produced by these buoyancy gradients, which is tilted and stretched in the updraft column. Fire whirls, which resemble dust devils, are often generated by fires (Figure 2) and can vary from common small whirls up to 5 m tall filled with flame to giant fire vortices approximately 0.5 km in diameter and several thousand meters tall, in which the entire smoke-filled convection column rotates. They can lift large burning embers and loft them far across the fire line, starting spot fires. They can be intense, and have been known to even break off trees that are more than 1 m in diameter. They may have a vorticity on the order of $1\text{--}10\text{ s}^{-1}$, though their radii are usually small and thus their rotational speeds do not reach the speeds within tornados. Fire whirls frequently occur where flow eddies occur, such as on the lee side of a fire, particularly near the outside edges of a fire front or when a fire is burning on the lee side of a ridge.

Forward bursts

A crown fire is one that spreads through the tree canopy, with or without a surface fire beneath. Flame lengths over 50 m along with spread rates over 3.5 m s^{-1} have been observed. If conditions for sustained spread through the crowns are not favorable, the trees will burn out, but a running crown fire can

Figure 2 A fire whirl is a spinning, moving column of ascending air containing flames that lifts smoke and debris. When seen along fire lines, whirls apparently range in diameter from tens of centimeters to small tornados in size and intensity, and are documented as having uprooted trees. Photograph from the International Crown Fire Modeling Experiment, 1997, courtesy of the Canadian Forest Service.

result when winds increase and the flames from one burning tree canopy are driven into adjacent trees. Crown fires can produce dramatic forward bursts of flame (Figure 3), allowing them to jump across firebreaks or rush uphill. Analysis of such an event captured in infrared imagery (Figure 4) by a research

Figure 3 Forward bursts from a crown fire prescribed burn during the International Crown Fire Modeling Experiment, 1997. Courtesy of the Canadian Forest Service.

Figure 4 A sequence of infrared images looking down on a crown fire climbing a slope (toward the upper right) from a research aircraft. Colors represent temperature, where yellow is hottest, and darker reds are cooler. The six images were taken 0.75 s apart. Note the hot yellow finger that shoots out 100 m suddenly in 1–2 s (frames 3–6); it then disappears. From Radke, L.F., Clark, T.L., Coen, J.L., et al., 2000. The wildfire experiment (WiFE): observations with airborne remote sensors. *Canadian Journal of Remote Sensing* 26, 406–417.

aircraft flying overhead showed a finger of flame burst forward 100 m at an estimated speed of 50 m s^{-1} and then dissipate within 2 s, leaving burning embers in its path. This type of explosive behavior results from an interaction between the atmospheric winds and the vorticity and winds produced by the fire.

Horizontal roll vortices and tree crown streets

After a fire has passed, crown fires are often seen to have left distinctive, sometimes unusual, patterns of burned and unburned trees. One example is 'streets,' where long strips of unburned tree vegetation are left amidst otherwise blackened areas; in one case one side of a row of trees was scorched, and the other side had few or no burn marks, indicating outward airflow from within the unburned street. These patterns have not been explained completely. It has been hypothesized that downward and outward flow of relatively cool air from horizontal roll vortices, perhaps from a tilting convection column, kept fire out of the crowns, and as it spreads outward in both directions near the ground, it caused the fire to leave these burned/unburned patterns. Sometimes the burn patterns are far more complex (Figure 5) with streets and swirl patterns, and may involve a sequence of formation and collapse of such rotating columns along the enlarging fire. Other explanations suggest that patterns such as this are the result of fluctuating wind speeds or directions.

Convective fingers

Fire lines moving across the landscape do not normally move in a straight line when driven by moderate ambient winds (about $3\text{--}4 \text{ m s}^{-1}$) but bow forward into parabolic fingers. The parabolic shape can be understood by examining how the convergence pattern produced under the fire's updraft is projected upon a straight fire line (Figure 6). In the absence of an ambient wind, a fire would create a vertically oriented

Figure 5 Burn scars ('fire streets') in yellow, unburned fuel in green, left after a fire burned through a North Carolina forest. Photograph courtesy of U.S.D.A. Forest Service.

Figure 6 The idealized structure of the near-surface wind convergence pattern beneath the convective updraft (stippled) of a fire line (driven by winds from the left, moving to the right). The convergence beneath the convective updraft draws the fire line forward in a bow shape. From Clark, T.L., Jenkins, M.A., Coen, J., Packham, D., 1996. A coupled atmospheric-fire model: convective feedback on fire-line dynamics. *Journal of Applied Meteorology* 35, 875–901. Copyright American Meteorological Society.

convective cell centered over itself, and draw air equally from all sides. However, in an ambient wind, shown in Figure 6 as coming from the left, assuming the convective column is tied to the fire at the surface and tilts downstream with height, the effect of downstream tilting is to shift the center of the low-level convergence pattern ahead of the fire front, drawing air at low levels (levels important to driving a fire) from different angles along the fire line, forming a curved inflow region at the fire front. Within a range of wind speeds, the stronger the wind, the stronger the tilt, and the farther forward the center of convergence lies. Stronger ambient winds may cause the convective column to break away and reform, complicating these interactions. Longer fire lines may form many protrusions, or 'fingers' along their length, as in the Onion fire, shown in Figure 7. The Onion fire produced fingers about 1 km wide apart only during times when an ambient wind was present. When the mean wind died down, the fire burned out the fuel between the fingers, once again forming a more linear and stalled smoldering fire line.

Blowups

A blowup is a sudden intensification and acceleration of burning during a fire. The burn rate may increase 500% and flame lengths can stretch 65 m above the trees. The convective updraft strengthens, pulling in surrounding air and further ventilating the fire. These firestorms create their own wind patterns, which have been strong enough to uproot trees and loft embers to start spot fires miles away. There is no definitive explanation of the cause of blowups, although they typically occur during the afternoon, with strong environmental wind

Figure 7 Convective fingers (spaced about 1 km apart) during the Onion fire. Photograph courtesy of Charles George, U.S.D.A. Forest Service. and fire-generated buoyancy-induced flow effects, and often in steep terrain. Current hypotheses suggest that interactions between combustion chemistry and fluid dynamics may be an essential part of blowup events, involving sudden mixing of fresh air with excess pyrolysis gases produced by radiative and convective heating within and ahead of the main flame zone.

Wildfire Impacts on Weather and the Environment

As well as responding to its atmospheric environment and changes in the weather, fire exerts its own impact. Wildland fires release heat ($1.74 \times 10^7 \text{ J kg}^{-1}$ of dry cellulose fuel burned), particulates (primarily composed of carbon), water vapor, carbon dioxide (CO_2), and an extraordinary spectrum of other gases including carbon monoxide (CO), hydrocarbons (HC), nitrogen oxides (NO_x), and sulfur oxides (SO_x). The released particulates are composed of both inorganic 'black' carbon and organic carbon (including fatty acids and toxic polycyclic aromatic hydrocarbons). The rate, composition, and emission factor for each chemical constituent (the mass release of each particular species per unit mass of fuel consumed) depends on the phase of combustion (whether the early, high-intensity flaming period, or a later low-intensity smoldering period), but these combustion characteristics themselves are affected by the plant species amount of biomass present, the size distribution of the fuel, precipitation history at the site, ambient atmospheric conditions, and other factors.

The smoke from fires can sometimes be traced thousands of kilometers in satellite images (see [Figure 8](#)). In 1998, smoke from thousands of Mexican fires reached the Southern United States. In other cases, pollutants from burns in Alberta, Canada, have been tracked to the Southeastern United States. Thus, the effect of wildland fires on the atmosphere, whether air pollution, impacts on cloud droplet distributions, or as a source of greenhouse gases, is not just a short-term local problem, but has regional or global impacts.

Figure 8 A SeaWiFS (Sea-viewing Wide Field-of-view Sensor) satellite image of the smoke from wildfires in Montana and Idaho on 8 August 2000. The smoke can be identified at least as far east as Illinois. Image provided by ORBIMAGE Orbital Imaging Corporation and processed by NASA Goddard Space Flight Center.

Emissions Components

Carbonaceous aerosol particles

Wildland fires vary widely in intensity (heat released per unit time) and severity (heat released per unit area). Shortly after ignition, a flaming phase continues for several minutes during which time the maximum release rates of heat, particles, and gases occur. Rate of fuel consumption is high, while the duration is very short. After flaming, some woody materials begin smoldering, with smoldering emissions decreasing exponentially with time. (In places with deep layers of duff or rotten wood, smoldering can continue for several hours to days, although in some cases fires that entrench in duff can smolder for months, depending on the depth and moisture of the duff and amount of rotten material, until snow falls.) The particle size distribution also varies between fires, with the most intense fires releasing the highest proportion of large particles and the most buoyant plumes, consuming 70–95% of available fuel. Many fires, however, only smolder, are of low intensity, burn a much smaller fraction of the available biomass, and emit nearly all fine particles in only slightly buoyant plumes. Biomass fires produce smoke particles in a bimodal distribution, with one peak in the 0.1–1.0 μm diameter range that spans the wavelengths of visible light (0.4–0.7 μm), and another in large particles over 10 μm in diameter.

Pollutants, nutrients, greenhouse gases, and VOCs

Wildland fires emit a variety of chemical gases, depending on fuel type, fuel chemistry, and fire behavior. These include long-lived greenhouse gases, e.g., CO_2 or CH_4 , as well as short-lived chemicals such as carbon monoxide (CO), nitrogen oxides (NO_x), hydrocarbons ($\text{C}_1\text{--C}_{12}$), partially oxidized hydrocarbons ((POHC) alcohols, aldehydes, ketones, and furans), halocarbons (CH_3X), sulfur compounds (carbonyl sulfide, dimethyl sulfide, dimethyl disulfide), and alkyl nitrates. Some of these emissions have important effects on the atmosphere: CO , non-methane hydrocarbons, and POHC influence the oxidative capacity of the atmosphere, and in the presence of NO_x lead to photochemical ozone formation on local and regional scales. Alkyl nitrates serving as a reservoir for NO_x might cause additional ozone formation in especially warm and pristine environments. Halocarbons, methyl chloride, and methyl bromide, released from fires are estimated to be 25% of the global budget, and are precursors to stratospheric ozone destruction. COS released by wildfires is a minor part of the global budget but is a precursor for sulfuric acid in stratosphere.

Mercury is another species released by wildfires. About half the atmospheric mercury comes from natural sources (in soil, oceans, and volcanoes), and the other half from human activity (including industrial pollution such as from coal-fired plants). Mercury is removed from the atmosphere through oxidation, creating ionic mercury in the troposphere and in clouds, where it then rains or dry deposits out to the surface. Contrary to the belief that this mercury is ‘lost,’ it may be taken up in the biomass and, when the biomass is consumed by fire, 95–99% of the mercury is emitted, 95% as gaseous mercury, and 5% as particulates. Studies estimate that mercury released by wildland fires may represent 25% of all anthropogenic sources.

Emission products including mercury can be lofted by the ‘smokestack effect’ deep into the atmosphere, where winds are

generally stronger, increasing the distance the emission products travel from their source. Intense wildland crown fires can produce heat fluxes on the order of 10 MW m^{-2} and a well-defined, strong updraft (50 m s^{-1} has been measured) over surface convergence. Aided by the water vapor released by combustion, intense fires can rapidly produce deep ‘pyrocumulus’ clouds over the fire (Figure 9), sometimes reaching the tropopause, with smoke trails visible from satellite flowing over 2000 km (Figure 8). These clouds can produce rain (thereby scavenging some of the smoke), hail, lightning, and strong surface winds such as microbursts, complicating fire behavior at the ground. As the fire burns less intensely and does not reach the critical temperature required to release flammable gases and sustain flaming combustion, it produces less heat, the air over the fire is less buoyant, smoke is not lofted as high, and it settles in valleys, where it can be trapped for days, improving only as it mixes with cleaner air.

Effect of Aerosol Particles on Cloud Microphysical and Radiative Transfer Properties

An important aspect of an extremely large portion of the aerosol particles released by fires is their ability to serve as cloud condensation nuclei (CCN) for droplets that evolve to form haze, fog, and clouds. When a fire is present, the concentrations released by fires can easily overwhelm the background concentration by factors of 2–50. *In situ* measurements of smoke-modified clouds in Mexico and Indonesia showed the cloud droplet concentrations were more than double those of unaffected clouds, increasing the droplet concentrations from 400 cm^{-3} to over 1000. Globally, they are estimated to be as plentiful as the other primary CCN sources – anthropogenic processes and the oceans. These particles increase cloud droplet

Figure 9 Smoke plume from a California wildfire. Photograph courtesy of the National Interagency Fire Center media library.

concentration, reducing cloud droplet size and narrowing the cloud droplet size distribution, and thus coalescence rate between droplets (the 'Twomey effect'), and perhaps the cloud's precipitation efficiency. This effect of reducing the average cloud particle radius also has been shown to increase the cloud's albedo, altering its radiative properties. This leads to the possibility of regional feedback, as widespread fires release particles that might in turn decrease the precipitation efficiency of clouds, exacerbating the dry conditions that favored the fires.

Hydrology and Land Surface Effects

Intense fires have had severe hydrological consequences, through their ability to influence the physical and chemical properties of soil, the ground flora, water-holding properties, and the capacity of soil to resist erosion. The combination of combustion and heat transfer during wildland fires produces steep temperature gradients in the surface layers of soil, as flame temperatures of 700–800 °C can occur. Heat produced by combustion of the material on the soil surface vaporizes organic substances, which are then moved downward in the soil until they reach cooler underlying soil layers, where they condense. After a fire, a layer of water-repellent soil resembling a waxy film may be found on the soil surface or a few centimeters below the burned area. Fire severity, behavior, soil properties, and temperature gradients developing in the soil during a fire all affect the formation of a water-repellent layer.

Watersheds damaged by intense fires can suffer increased runoff, greater erosion, and greater sedimentation rates, resulting in mudslides, silted-out reservoirs and streams, and the potential for flooding. The longevity of these effects from weak fires and prescribed burns is generally limited to less than a year, but water repellency caused by a severe fire burning through large fuel accumulations can extend over several years. Current research is investigating whether fires can change the surface albedo and other properties enough to affect mesoscale land surface processes and change precipitation patterns.

Introduction

Inadvertent weather modification refers to any changes in the weather resulting from human actions done for purposes other than changing the weather. Human activities have accidentally been able to change all facets of the weather at and near the Earth's surface. For example, major cities change every facet of their weather, including the number of thunderstorms; large irrigated areas create clouds and rainfall when conditions are right; and jet aircraft often create cirrus clouds. The list of accidental weather changes is almost endless. However, many such changes in the atmosphere from human changes in the biosphere have been relatively localized, and their effects typically create weather changes occurring on scales ranging from 1 km² up to 10 000 km².

Knowledge that humans were altering the weather became commonplace about 200 years ago as residents of many of Europe's larger cities recognized that urban areas had poorer visibility due to the increase in haze and smoke and higher temperatures than did their surrounding rural areas. Serious studies of urban effects on weather developed in Europe in the nineteenth century and intensified as networks of surface weather stations yielded data that allowed scientists to define the patterns of temperature, humidity, and precipitation in and around cities. The industrial revolution began in the nineteenth century and led to many more weather changes. For example, by 1880 scientists in England discovered that more rainfall occurred on work days, Monday through Friday, than on nonwork days (Saturday and Sunday), a result correctly assessed as an effect of industrial pollutants.

The growth of meteorological knowledge about the atmosphere's behavior, which expanded rapidly during the twentieth century, brought forward investigations of how other land use changes by humans and the emissions from factories and vehicles altered the weather. Progress in detecting and understanding inadvertent weather modification came rapidly in the latter half of the twentieth century as new remote sensors, including satellites and radars, made it much easier to detect and measure conditions. Major advances in meteorological knowledge now allow use of numerical modeling to estimate urban heat islands and other weather anomalies. Interest in and concern over inadvertent weather changes grew as the recognition of the widespread and significant magnitude of these changes developed among the citizenry and public officials. The weather changes accidentally wrought by human activities translate into climate changes when the weather change becomes frequent and significantly different from the climate values expected in a natural, unaffected environment. **Figure 1** shows the average summer pattern of thunderstorms around St. Louis, MO, revealing a localized increase from about 16 storm days per summer in the region's rural areas to a peak of 28 days in and east of the city. Studies of individual summer days revealed those days when the weather conditions were

changed sufficiently by St. Louis to initiate thunderstorms. For example, in one summer 7 added storm days occurred over the city, whereas 16 added storm days were created in the following summer, revealing the large year-to-year variability that exists in most inadvertent weather changes. Many inadvertent weather changes are intermittent and depend on the type of natural weather conditions existing.

Atmospheric Processes Changed

Changes that humans have made to the biosphere that translate into effects on various atmospheric processes include

- surface color (albedo);
- surface topography (roughness) and orientation;
- subsurface materials (soils) including their thermal conductivity, thermal capacity, and hydraulic conductivity;
- artificial sources and sinks of heat, moisture, and mass;
- heat released naturally or artificially at the ground;
- amount of water and dust;
- biota.

Basically, the above changes result from two major human activities: changes in the existing natural land use, and emissions of gases and particles as a result of combustion. Acting individually or in concert, these characteristics affect certain basic processes of exchange between the biosphere and the atmosphere, which, in turn are themselves interactive. These exchange processes include

- the sensible heat budget;
- the moisture budget;
- momentum exchange;
- mass (other than water) exchange;
- atmospheric electrical exchange properties.

Alterations in these exchange processes affect a wide variety of weather conditions. Those commonly altered are at the surface and in the low levels of the atmosphere and include

- radiation;
- temperature;
- humidity;
- wind speed and direction;
- visibility (fog and haze).

These changes are further associated with changes in conditions extending farther aloft in the atmosphere including clouds, precipitation, and storminess. Microphysical processes in clouds are changed by urban and industrial emissions of various particles, including soluble aerosols and ice nuclei, as well as by additional moisture and enhanced vertical air motions. Emissions of some trace gases, such as sulfur dioxide from the burning of coal, can also lead to new particle formation and altered cloud properties. In some instances,

Figure 1 Pattern based on the average number of summer thunderstorms in and around the St. Louis, MO, urban area.

emissions are injected into the upper atmosphere by high-flying aircraft.

Effects of Changed Land Use Conditions

The description of what has been found about inadvertent weather modification is organized around land use types and emissions.

Urban Areas

A major means whereby humans have affected weather has been through the creation of urban environments. In the thirteenth century, residents of London first noted that the city had temperatures and fogs different from those in surrounding rural areas. The industrial revolution and associated rapid growth of cities that began in the nineteenth century resulted in significant local- and regional-scale changes in weather both in and near urban locales. Even small towns of a few thousand population create an effect on temperatures and have an 'urban heat island,' and large cities like New York create much higher temperatures ranging from 3 to 7 °C above rural values.

Cities are major converters of energy and matter, and their products affect the heat and moisture budgets as well as the exchange of mass into the atmosphere. Hence, urban areas alter all forms of weather. The list of changes includes increased contaminants in the air, less solar radiation, higher temperatures, decreased visibility, lower humidity, altered wind speed and direction, greater cloudiness, added precipitation, altered atmospheric electricity, added severe weather events, and changes to mesoscale synoptic weather conditions including fronts. The degree of change in any of these elements at any given time depends upon (1) the areal extent of the urban complex, (2) its industrial types, (3) its juxtaposition to large water bodies and topographic features such as mountain ranges, (4) the time of day, (5) the type of natural background weather system present at any given time, (6) the season of the year, and (7) the climate. Urban areas often act as mechanical barriers to low-level airflow and can even retard the action of

fronts. Temporal differences produced by cities can be illustrated by solar radiation, which is decreased by urban aerosols, and the decrease is much greater in winter than in summer, is decreased more on weekdays than weekends, and is decreased more in the morning than in the afternoon.

Figure 2 shows the long-term frequencies of smoke and haze days as measured at several US Midwestern cities of varying sizes. These visibility-related data are quantitative surrogates of the effects of growing cities and are the only type of pollutant-related data systematically collected since the start of the twentieth century. Chicago, the largest of the cities considered, was the first to show an increase and one that rapidly became sizable; smaller industrial cities like Moline, Springfield, and Peoria also showed increases beginning later in the 1930s and 1940s. The only small nonindustrial city, Cairo, has no apparent increase.

Weather changes resulting from urbanization are summarized in **Table 1**. Changes that are easy to measure include visibility, temperature, and winds. Visibility in and downwind of a major city is usually diminished. The most radical change produced by a city is in the heat balance. In-city temperatures are generally higher than nearby rural values, the difference being greatest at night, but in the early morning the urban temperatures are sometimes slightly lower than rural values. Heat-island effects have been measured in hundreds of cities of widely varying sizes and climates, and can now be numerically modeled based on the urban size and shape. The daytime urban-generated heating can extend vertically up to several thousand meters above a large city, and in some situations a heat plume extends downwind of the city. Urban areas also act as physical obstacles to low-level winds, decreasing their speeds in the city and altering wind directions near the surface. When low wind speeds are present, a rural-to-urban circulation pattern often develops.

Figure 2 Temporal distribution of the annual number of days with smoke and/or haze affecting visibility at selected US Midwestern cities of varying sizes.

Table 1 Average weather changes resulting from urbanization, as measured at many cities in varying climatic zones

	<i>Annual</i>	<i>Cold season</i>	<i>Warm season</i>
Contaminants (volume)	+1000%	+2000%	+500%
Solar radiation (Langleys)	−22%	−34%	−20%
Temperature (°C)	+2	+3	+1
Humidity (relative)	−6%	−3%	−8%
Visibility (frequency)	−26%	−34%	−17%
Fog (frequency)	+60%	+100%	+30%
Wind speed	−25%	−20%	−30%
Cloud frequency	+8%	+5%	+10%
Rainfall amount	+14%	+13%	+15%
Snowfall amount	+10%	+10%	−
Thunderstorm frequency	+16%	+5%	+30%

Urban weather changes that are more difficult to measure include alterations in humidity, fogginess, cloudiness, precipitation, snowfall, solar radiation, atmospheric electricity, and severe weather. Humidities over cities are generally decreased because there is less evapotranspiration from urban areas than from rural areas owing to the presence of hard surfaces and the lack of plants. However, certain urban-located industrial activities release large volumes of moisture from combustion and cooling devices.

Various urban–industrial complexes affect clouds, precipitation, and related severe weather conditions. These effects are difficult to measure and often extend 5–50 km beyond the city. In general, only large cities, typically those with populations exceeding one million, create localized changes in clouds and related precipitation processes. A major field study centered on St. Louis in the 1970s defined how a city alters clouds and precipitation. Clouds and the formation of precipitation depend on vertical motions in the atmosphere, the presence of adequate moisture, and small particles that serve as cloud and raindrop nuclei. St. Louis often deflected the low-level airflow, resulting in a convergence zone in the lee of the city, a condition that enhanced vertical motions, as did the heat being released by the city. The city was also a source of various aerosols, including cloud condensation nuclei essential to cloud droplet formation, and certain industrial emissions were found to add freezing nuclei, a key to raindrop formation. Cities are complex rainmakers. In the warm season, the enhanced convection also led to more thunderstorms and hail in and east of the city.

Industrial Complexes

Some industrial complexes are isolated away from cities, and certain such rurally located industrial centers that produce large releases of moisture, heat, and particles have been found to create measurable localized weather changes. For example, power generating plants, largely through the release of moisture and latent heat from cooling lakes or towers, have been found to create frequent fogs, icing, and clouds, and in some instances, rain and snow showers. These effects are most common in winter. Large fires from natural gas fields have been noted to create clouds and sometimes rain.

Nonagricultural Rural Areas

This land use category embraces large portions of the Earth's land surface and includes deserts, swamps, grasslands, forests, and high-altitude barren areas. Deserts have been modified by overgrazing, warfare, and overcultivation, and these activities have loosened the surface, causing soil deflation. The resulting dust added to the atmosphere alters the regional radiation budget. Deforestation leads to increases in solar radiation at the surface, altering surface temperatures and evapotranspiration. Deforestation in eastern Europe was found to have led to less rainfall, and in more tropical areas deforestation has led to greater temperature extremes and altered rainfall. Human alteration of natural grasslands, largely by converting them to pasture lands, has led to overgrazing and some dramatic changes in weather, including less cloudiness and decreases in rainfall. The drainage of wetlands and swamps has produced small-scale effects on surface conditions, including higher surface temperatures.

Agricultural Areas

All forms of agricultural land use affect the weather, including cultivated fields, pastures, orchards, and planned forests. The burning of agricultural residues in certain areas of the world adds heat and particles, and in turn these reduce visibility, reduce incoming solar radiation, change clouds, and, in some instances, decrease rainfall from the addition of too many cloud condensation nuclei. Irrigation over large areas changes the surface albedo and adds moisture to the atmosphere. In some climate zones such as the High Plains of the United States, large-scale irrigation has increased clouds and rainfall in and beyond the irrigated area. Different crops have different transpiration rates, leading to soil moisture differences, and when different crops are adjacent and planted over large areas the resulting moisture differences affect the boundary-layer structure. This can alter mesoscale wind conditions and can lead to convection, clouds, and rainfall. Other weather changes from agricultural activities include the use of hedgerows, which decrease wind speeds, and crop spraying, which adds micro-sized particles capable of affecting cloud formation.

Marine Areas

The creation of large reservoirs in certain drier climates has led to increased clouds under certain conditions. The potential for purposefully modifying the weather in dry areas using reservoirs has been explored and modeled to ascertain the possible effects on clouds and rainfall.

Transportation Corridors

The exhaust from high-flying aircraft often leads to contrails, which in high-frequency flight corridors leads to shields of cirrus clouds covering thousands of square kilometers. In parts of the central United States, contrail-generated cirrus has increased the number of cloudy days by 30%. These added clouds have also decreased surface daytime temperatures. Heat and particulate emissions from

vehicles on high-density transportation corridors sometimes lead to fogs and decreased visibility along and adjacent to the corridors.
